Abstract

Background: Gastrointestinal stromal tumors (GISTs), the most common type of mesenchymal tumors of the gastrointestinal (GI) tract, demonstrate positive kit staining. We report our surgical experience with 100 small intestine GIST patients and identify predictors for long-term disease-free survival (DFS) and overall survival (OS) to clarify the difference between high- and low-risk patients.

Methods: The clinicopathologic and follow-up records of 100 small intestine GIST patients who were treated at Chung Gung Memorial Hospital between 1983 and 2002 were retrospectively reviewed. Clinical and pathological factors were assessed for long-term DFS and OS by using a univariate log-rank test and a multivariate Cox proportional hazard model.

Results: The patients included 52 men and 48 women. Their ages ranged from 27 to 82 years. Among the 85 patients who underwent curative resection, 44 (51.8%) developed disease recurrence (liver metastasis was the most common form of recurrence). The follow-up period ranged from 5 to 202 months (median: 33.2 months). The 1-, 3-, and 5-year DFS and OS rates were 85.2%, 53.8%, and 43.7%, and 91.5%, 66.6%, and 50.5%, respectively. Using multivariate analysis, it was found that high tumor cellularity, mitotic count >5/50 high-power field, and a Ki-67 index >10% were three independent factors that were inversely associated with DFS. However, absence of tumor perforation, mitotic count < 5/50 high power field, and tumor with low cellularity were predictors of long-term favorable OS.

Conclusion: Tumors with low cellularity, low mitotic count, and low Ki-67 index, which indicate low risk, predict a more favorable DFS for small intestine GIST patients undergoing curative resection. Absence of tumor perforation with low mitotic count and low cellularity, which indicates low risk, can predict long-term OS for small intestine GIST patients who have undergone curative resection.
Background
Mesenchymal tumors of the gastrointestinal (GI) tract are rare, comprising only 0.1% to 3% of all GI neoplasms [1]. Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the GI tract. These tumors are composed of tumor cells from the interstitial cells of Cajal [2,3], which are considered to be GI pacemaker cells.

Gain-of-function mutations in the c-kit proto-oncogene and overexpression of the kit protein can occur [4,5], and result in a constitutive stimulus to tumor cell growth. Because the kit tyrosine kinase inhibitor imatinib mesylate (Gleevec, formerly known as STI571, Novartis Pharma AG, Basel, Switzerland) has been shown to produce a promising clinical result in an advanced GIST patient [6], identification of GIST by kit immunopositivity has become paramount.

Surgical resection with a negative gross margin remains the mainstay of therapy for primary GISTs. However, recurrence is common, and the 5-year survival rate after complete resection ranges from 40% to 65% [7-11]. Several clinical and pathological factors that influence patient survival have been reported, but the results have varied due to variation in confirmation of kit [7-12]. Postoperative follow-up and management for small intestine GISTs after curative resection should be tailored to patients according to high- or low-risk status of the tumors. Before the era of imatinib mesylate, we identified 100 patients with primary GISTs of the small intestine using positive kit immunostaining. Our aim was to identify predictors for long-term DFS and OS for small intestine GIST patients and clarify the difference between low- and high-risk patients after curative resection.

Methods
One hundred sixty-seven consecutive patients with mesenchymal tumors involving the small intestine were treated at the Department of Surgery, Chang Gung Memorial Hospital from January 1983 to December 2002. The study was conducted with the approval of the institutional ethics board of our hospital. We excluded (a) patients with other intra-abdominal or retroperitoneal sarcomas which directly invaded or metastasized to the small intestine (such as uterine leiomyosarcoma, gastric GISTs, retroperitoneal sarcoma, etc.), (b) patients with other concurrent malignancies at presentation, and (c) patients with incidental findings on laparotomy (most had benign leiomyoma, size < 2 cm and trace mitotic count).

Immunohistochemistry (IHC) analyses were performed to identify immunophenotypes and reviewed blindly by the authors (Wu TJ, Lee LY, Yeh CN, and Wu PU). Thirteen of 113 patients who showed negative kit immunostaining were excluded from the study including 5 patients with leiomyomas, 3 with leiomyosarcomas, 1 with a schwannoma, 1 with an inflammatory fibroid polyp, 1 with a follicular dendritic tumor, 1 with a malignant rhomboid tumor, and 1 with a malignant histiocytic sarcoma. One hundred patients were diagnosed as having primary GISTs of the small intestine according to established criteria [13,14]. Clinicopathological features and follow-up status of these patients were retrospectively reviewed.

Immunohistochemistry (IHC)
Four-µm sections from formalin-fixed, paraffin-embedded tissue were stained for ICC-associated antigens (kit and CD34) (Dako, Carpinteria, California, USA), myogenic antigen (smooth muscle actin [SMA]) (Dako, Carpinteria, California, USA), neurogenic antigen (S-100) (Dako, Carpinteria, California, USA), and tumor proliferation marker (Ki-67) (Dako, Carpinteria, California, USA). A biotin/straptavidin-peroxidase complex detection system (Dako, Carpinteria, California, USA) with diaminobenzidine (DAB) as the chromogen was used. Normal small intestine was used as the internal control for kit, SMA and S-100. The vascular endothelium was an internal positive control for CD34, and small intestine mucosa was an internal control for Ki-67. For IHC scoring, cells with positive stains below 10% were regarded as negative, 10%–50% as focally positive, and over 50% as diffusely positive. A Ki-67 index greater than 10% positively stained nuclei in 50 randomly selected high power fields (HPF) was defined as the cut line [15].

Prognosis analysis
Patients with distant metastases or multiple small tumors involving whole small intestine (sarcomatosis) at presentation were defined as advanced cases. A curative resection was defined as the tumor having been completely removed with a negative margin macroscopically. Recurrent disease was defined as the presence of a histologically or radiographically demonstrated tumor. Distant metastatic disease was defined as disease occurring at remote structures. Regional intra-peritoneal disease was called local recurrence if it involved a solitary recurrent tumor or sarcomatosis.

The following clinical and pathological factors were chosen for survival analysis: gender, age (<60 or ≥60 years), operative time (elective, non-elective [urgent or emergent]), operative procedure, location, tumor size (<2 cm, 2–5 cm, 5–10 cm, or ≥10 cm), mesenteric involvement, local invasion to other intra-abdominal organs or peritoneum, tumor perforation, cell type (spindle or mixed with epithelioid cells), pleomorphism (low or high), mitotic count (≤5 or >5 of 50 HPF), cellularity (low or high), nuclear atypia, para-nuclear cytoplasmic vacuoles, skeinoid fibers, inflammatory cell infiltration, tumor border,
tumor necrosis, mucosal invasion, ulceration, vascular proliferation, microscopic resection margins, lymphatic infiltration, immunophenotype (kit, CD34, SMA, and S-100), and Ki-67 index (<10% or ≥10%).

Data were analyzed using SPSS software (version 10.0; SPSS, Inc., Chicago, Illinois, USA). DFS and OS rates were calculated using the Kaplan-Meier method. Survival was calculated from the day of the histological diagnosis to the closing date for the evaluation of follow-up, which was December 31, 2003. The log-rank test was used for univariate analysis and Cox's proportional hazard model was used for multivariate analysis. P < 0.05 was considered significant.

**Results**

**Clinical characteristics**

Fifty-two males and 48 females who ranged in age from 27 to 82 years (median: 56.5 years) were symptomatic at presentation. The most common symptom was GI bleeding (n = 84), followed by abdominal pain (n = 38), anemia (n = 34), and palpable mass (n = 33). Peritonitis due to tumor perforation was found in 12 patients.

Regarding tumor location, 19 tumors were located in the duodenum (10 in the second portion; 6 in the third; and 3 in the fourth portion), 63 in the jejunum, and 17 in the ileum. One patient, who presented with multiple tumors distributed throughout the small intestine and mesentery, was classified as undetermined location. Regarding the jejunal tumors, most occurred in the proximal jejunum, with a median distance of 30 cm from the Treiz ligament. Most of the ilial tumors developed in the distal ileum, with a median distance of 60 cm from the ileocecal junction. The largest tumor diameter ranged from 3 to 30 cm (median: 8.8 cm).

Four commonly used diagnostic tools were computed tomography (CT) (78%), panendoscopy (66%), upper GI series (44%), and angiography (23%). Among the 78 patients who underwent CT, CT images revealed the presence of an intra-abdominal tumor in 71 patients, yielding a sensitivity rate of 91.0%. Routine esophagogastroduodenoscopy was performed to evaluate patients with upper GI bleeding, but only 11 of the 66 patients (16.7%) with duodenal tumors had endoscopic abnormalities. The upper GI series showed abnormal findings in 34 of the 44 tested patients (77.3%). Although half of the patients suffered from melena, only 11 of the 23 patients (43.5%) who underwent angiography had positive angiographic findings.

**Histopathologic features**

Most tumors were composed of spindle cells (83%), and some were mixed with epithelioid cells (17%). No purely epithelioid picture was seen in our series. Tumor cells were mostly uniform, but some revealed significant pleomorphisms (32%). Focal nuclear atypia was a common feature (93%), with some tumors showing scattered bizarre nuclei. However, para-nuclear cytoplasmic vacuoles (10%) and skeneoid fibers (14%) were rarely found. Mitoses were common in the small intestine GISTs; 69% of patients had a mitotic count > 5 per 50 HPF and 31% of patients had a count <5 per 50 HPF. Coagulative necrosis (68%), mucosal ulceration (55%), and high cellularity (43%) were usually found in the larger tumors (> 5 cm). Most tumors were rich in vascular proliferation (90%), and stromal hemorrhage was a common feature of these tumors. Three patients had lymphatic infiltration.

With regard to staining distribution, most small intestine GISTs (80/100; 80%) showed diffusely positive kit immunostaining, and some showed focally positive immunostaining (20%). Most of the staining patterns showed diffuse, strong cytoplasmic positivity (69%), and some (31%) showed a mixed cytoplasmic dot-like pattern (the so-called "golgi pattern"). Sixty-eight of 100 tumors showed CD34 positivity. 35% showed myogenic differentiation that was diffusely positive in SMA, and 24% showed neurogenic differentiation that was diffusely positive for S-100 protein.

**Treatment and outcomes**

Among the 100 patients, 86 underwent segmental resection of the small intestine with the tumor and the involved mesentery, peritoneum, retroperitoneum, or other contiguous intra-abdominal organs. Six patients with a tumor in the second portion of the duodenum underwent the Whipple procedure, and the other 7 patients with isolated tumors underwent local excision. The remaining patient, who presented with sarcomatosis, underwent biopsy. Elective surgery was scheduled for 72 patients; for the other 28 patients non-elective (urgent or emergent) operations were performed due to active tumor bleeding, tumor perforation-related peritonitis, or intestinal obstruction. There was no postoperative mortality in this series; hospital stays ranged from 6 to 54 days (median: 15 days). With a median follow-up of 33.2 months (range: 5–202 months), the OS rates for these 100 patients were 91.5% at 1 year, 66.6% at 3 years, and 50.5% at 5 years.

Curative resection was carried out in 85 patients. Of the 15 patients who did not undergo curative resection, 10 had liver metastasis, 4 had debulking resection due to invasion of great vessels or vital organs, and 1 had open biopsy for sarcomatosis. Patients who underwent curative resection had a significantly longer median survival of 123.3 months (mean: 97.5 months; range: 5.5–202 months) compared with 12.0 months (mean: 21.4 months).
months; range: 4–56 months) for those who had incomplete resection or distant metastasis at presentation. Of 85 patients who underwent curative resection, 44 (51.8%) had recurrence. The median time of recurrence was 20.5 months (range: 3.7–125.1 months). The DFS rates were 85.2% at 1 year, 53.8% at 3 years, and 43.7% at 5 years.

Table 1 lists the sites of recurrence. Most cases of liver metastasis were multiple. Only 4 patients with isolated liver metastasis underwent hepatectomy. For the 44 patients with recurrence, median post-recurrence survival was 7.9 months (range: 1.2–90 months). Complete re-resection for recurrent disease was only achieved in 8 patients, with a median post-recurrence survival of 25.8 months. Chemotherapy (doxorubicin [adriamycin] and dacarbazine [DTIC]) was given to 5 patients who had a median survival of 3.6 months. Thirty-one patients with recurrence were given supportive treatment. These patients had a median survival of 5.9 months. Since 2002, imatinib mesylate (Gleevec) has been administered for unresectable GISTs in our hospital. Eight patients with unresectable recurrent disease were given this therapy.

Survival analysis

Regarding clinical factors, large tumor size, advanced tumor with local invasion to a contiguous organ, and presence of tumor perforation predicted poor DFS (Table 2). Among pathological factors, mitotic count > 5 per 50 HPF, high cellularity, presence of tumor necrosis, and Ki-67 index ≥10% predicted worse DFS (Tables 3 and 4). However, multivariate survival analysis revealed that tumor with high cellularity (Fig. 1A), mitotic count >5 per 50 HPF (Fig. 1B), and a Ki-67 index ≥10% (Fig. 1C) were independent factors that predicted poor DFS (Table 5).

With regard to OS, presence of tumor perforation, mitotic count >5 per 50 HPF, high cellularity, presence of tumor necrosis, vascular proliferation, lymphatic infiltration, and Ki-67 index ≥10% predicted worse OS by univariate analysis (Tables 2, 3, and 4). However, presence of tumor perforation (Fig. 1D), mitotic count >5 per 50 HPF (Fig. 1E), and tumor with high cellularity (Fig. 1F) independently predicted less favorable OS (Table 5).

Table 1: Sites of first recurrence in small intestine GIST patients who underwent curative resection

| Recurrence site | N | % of total recurrence |
|-----------------|---|-----------------------|
| Liver           | 35 | 79.5                  |
| Any             | 14 | 31.8                  |
| Only            | 21 | 47.7                  |
| Intra-abdominal  | 21 | 47.7                  |
| Any             | 13 | 29.5                  |
| Only            | 8  | 18.2                  |
| Lung            | 1  | 2.3                   |
| Bone            | 1  | 2.3                   |

Table 2: Prognostic analysis of DFS and OS for GISTs of the small intestine in terms of clinical features

| Variable                   | Mean DFS (months; 95%CI of mean) | P     | Mean OS (months; 95%CI of mean) | P     |

DFS = disease-free survival; OS = overall survival; GISTs = gastrointestinal stromal tumors
Discussions and conclusions

Gastrointestinal stromal tumors (GISTs) comprise the great majority of primary mesenchymal tumors of the gastrointestinal (GI) tract. The small intestine is the second most common site of occurrence [9-11,17-21]. Prognosis for patients with GISTs depends to some extent on the anatomic site of tumor location. According to some authors, there is a trend for small intestine tumors to have the worst prognosis and esophageal tumors the best [10,20]. However, some other authors have concluded that the behavior of GISTs is similar regardless of site [10,12,21]. Due to the controversy over the topic of anatomic variation, we focused specifically on GISTs of the small intestine. We retrospectively reviewed 100 GISTs with c-kit immunopositivity at one institution over two decades. This study is one of the largest series [20,24-26], especially before the imatinib mesylate era.

The 1-, 3-, and 5-year DFS rates following curative resection in our study were 85.2%, 53.8%, and 43.7%, respectively, which are similar to those in DeMatteo's report [11] and better than those reported by Crosby et al [20]. The OS rate was 50.5% at 5 years, which is similar to rates reported in the literature which range from 40% to 65% [8-11,22]. In this study, we used univariate and multivariate analysis to analyze DFS and OS for patients with small bowel GISTs after curative resection with regard to numerous clinicopathologic factors. The results can be used to clarify the difference between high- and low-risk patients after curative resection to further tailor follow-up programs and treatment plans.

In univariate analysis, tumor size, local invasion, tumor perforation, mitotic count, tumor cellularity, tumor necrosis, and Ki-67 index significantly influenced DFS in patients with small intestine GISTs after curative resection. Also, tumor size, tumor perforation, mitotic count, tumor cellularity, tumor necrosis, vascular proliferation, lymphatic infiltration, and Ki-67 index significantly influenced OS. Application of the multivariate Cox proportion

Table 3: Prognostic analysis of DFS and OS for GISTs of the small intestine in terms of histopathological features

| Variable | Mean DFS (months; 95%CI of mean) | P | Mean OS (months; 95%CI of mean) | P |

| Ki-67 index ≥ 10%      |               |                          |         |

DFS = disease-free survival; OS = overall survival; GISTs = gastrointestinal stromal tumors; CI = confidence interval
Tumor size was one of factors that predicted prognosis for GIST in a consensus report [13], which defined high risk if tumor size was more than 10 cm and intermediate risk if tumor size ranged from 5 to 10 cm. However, tumor size was not an independent risk factor in our study. It might be there was patient selection bias in this study, in which most of the patients who received surgical treatment were symptomatic and had a large tumor (median tumor size was 8.8 cm, range from 3 to 30 cm). It also might be biased because of the poor prognosis of small intestine GIST, in which tumor size over 5 cm is defined as probably malignant [27]. Therefore, there is no significant difference between tumors of size >10 cm and tumors from 5 to 10 cm in size.

Mitotic count < 5/50 HPF, low cellularity, no tumor necrosis, and low Ki-67 index were associated with favorable DFS, but only mitotic count >5/50 HPF and high Ki-67 index had a significant adverse influence on DFS. Some authors have also proposed that high histopathologic grade adversely affects prognosis of gastrointestinal sarcoma [8-10]. GISTs of the small intestine with histopathologic features including mitotic counts >5/50 HPF, high cellularity, absence of a predominant organoid growth pattern, absence of skeinoid fibers, presence of severe nuclear pleomorphism, presence of mucosal infiltration, and tumor cell necrosis have been significantly associated with an adverse outcome in the literature [24-26]. However, Crosby et al. [20] found no correlation between tumor grade and clinical behavior in 50 GISTs of the small intestine. In the present study, mitotic count >5/50 HPF was the most important independent factor predicting poor DFS and OS. Similar to Miettinen's report, kit immunopositivity, staining patterns, and histologic subtype did not correlate with prognosis [21]. Ki-67 immunoreactivity appears to be a valid measure of tumor cell proliferation and has been related to outcome in patients with GISTs in a number of studies [22,23]. Tumors with more than 10% of nuclei positive for Ki-67 analogs developed metastases more easily and had higher tumor-related mortality [15].

Figure 1
Disease-free survival for 85 patients with small bowel gastrointestinal stromal tumor (GIST) who underwent curative resection in terms of (A) mitotic count; (B) tumor cellularity; (C) Ki-67 index; and overall survival for 85 patients with small bowel GIST who underwent curative resection in terms of (D) tumor perforation; (E) mitotic count; (F) cellularity.
In the present study, Ki-67 score ≥10% was also an independent factor associated with poorer DFS, however, it was not an independent factor for OS. Mitotic count is superior to Ki-67 index analogs in the evaluation of GIST with regard to DFS and OS.

In conclusion, small tumor size with low mitotic counts and low Ki-67 index, indicating low risk, predicted more favorable DFS of small intestine GIST patients who underwent curative resection. Absence of tumor perforation with low mitotic count and low cellularity, indicating low risk, predicted long-term OS of small intestine GIST patients who underwent curative resection.
