On the Classification of All Self-Dual Additive Codes over GF(4) of Length up to 12

Lars Eirik Danielsen* Matthew G. Parker*

February 17, 2006

Abstract

We consider additive codes over GF(4) that are self-dual with respect to the Hermitian trace inner product. Such codes have a well-known interpretation as quantum codes and correspond to isotropic systems. It has also been shown that these codes can be represented as graphs, and that two codes are equivalent if and only if the corresponding graphs are equivalent with respect to local complementation and graph isomorphism. We use these facts to classify all codes of length up to 12, where previously only all codes of length up to 9 were known. We also classify all extremal Type II codes of length 14. Finally, we find that the smallest Type I and Type II codes with trivial automorphism group have length 9 and 12, respectively.

Keywords: Self-dual codes; Graphs; Local complementation

1 Introduction

An additive code, \( C \), over GF(4) of length \( n \) is an additive subgroup of GF(4)^n. \( C \) contains \( 2^k \) codewords for some \( 0 \leq k \leq 2n \), and can be defined by a \( k \times n \) generator matrix, with entries from GF(4), whose rows span \( C \) additively. \( C \) is called an \( (n, 2^k) \) code. We denote GF(4) = \{0, 1, \( \omega \), \( \omega^2 \)\}, where \( \omega^2 = \omega + 1 \).

Conjugation of \( x \in \text{GF}(4) \) is defined by \( \overline{x} = x^2 \). The trace map, \( \text{Tr} : \text{GF}(4) \to \text{GF}(2) \), is defined by \( \text{Tr}(x) = x + \overline{x} \). The Hermitian trace inner product of two vectors over GF(4) of length \( n \), \( u = (u_1, u_2, \ldots, u_n) \) and \( v = (v_1, v_2, \ldots, v_n) \), is given by

\[
\mathbf{u} \ast \mathbf{v} = \text{Tr}(\mathbf{u} \cdot \mathbf{v}) = \sum_{i=1}^{n} \text{Tr}(u_i v_i) = \sum_{i=1}^{n} (u_i v_i^2 + u_i^2 v_i) \pmod{2}. \tag{1}
\]

Note that \( \mathbf{u} \ast \mathbf{v} \) is also the number (modulo 2) of places where \( \mathbf{u} \) and \( \mathbf{v} \) have different non-zero values. We define the dual of the code \( C \) with respect to the Hermitian trace inner product, \( C^\perp = \{ \mathbf{u} \in \text{GF}(4)^n \mid \mathbf{u} \ast \mathbf{c} = 0 \text{ for all } \mathbf{c} \in C \} \). \( C \) is self-orthogonal if \( C \subseteq C^\perp \). It has been shown that self-orthogonal additive codes over GF(4) can be used to represent quantum error-correcting codes.
codes \([4]\). If \(C = C^\perp\), then \(C\) is self-dual and must be an \((n, 2^n)\) code. Self-dual additive codes over GF(4) correspond to zero-dimensional quantum codes, which represent single quantum states. If the code has high minimum distance, the corresponding quantum state is highly entangled.

The Hamming weight of \(u\), denoted \(\text{wt}(u)\), is the number of nonzero components of \(u\). The Hamming distance between \(u\) and \(v\) is \(\text{wt}(u - v)\). The minimum distance of the code \(C\) is the minimal Hamming distance between any two distinct codewords of \(C\). Since \(C\) is an additive code, the minimum distance is also given by the smallest nonzero weight of any codeword in \(C\). A code with minimum distance \(d\) is called an \((n, 2^k, d)\) code. The weight distribution of the code \(C\) is the sequence \((A_0, A_1, \ldots, A_n)\), where \(A_i\) is the number of codewords of weight \(i\). The weight enumerator of \(C\) is the polynomial

\[
W(x, y) = \sum_{i=0}^{n} A_i x^{n-i} y^i
\]  

We distinguish between two types of self-dual additive codes over GF(4). A code is of Type II if all codewords have even weight, otherwise it is of Type I. It can be shown that a Type II code must have even length. Bounds on the minimum distance of self-dual codes were given by Rains and Sloane [19, Theorem 33]. Let \(d_I\) be the minimum distance of a Type I code of length \(n\). Then \(d_I\) is upper-bounded by

\[
d_I \leq \begin{cases} 
2 \left\lfloor \frac{n}{6} \right\rfloor + 1, & \text{if } n \equiv 0 \pmod{6} \\
2 \left\lfloor \frac{n}{6} \right\rfloor + 3, & \text{if } n \equiv 5 \pmod{6} \\
2 \left\lfloor \frac{n}{6} \right\rfloor + 2, & \text{otherwise}.
\end{cases}
\]  

(3)

There is a similar bound on \(d_{II}\), the minimum distance of a Type II code of length \(n\),

\[
d_{II} \leq 2 \left\lfloor \frac{n}{6} \right\rfloor + 2.
\]  

(4)

A code that meets the appropriate bound is called extremal. It can be shown that extremal Type II codes must have a unique weight enumerator. Rains and Sloane [19] also used a linear programming bound, and showed that extremal codes do not exist for all lengths. For instance, there is no self-dual \((13, 2^{13}, 6)\) code. If a code has highest possible minimum distance, but is not extremal, it is called optimal. An interesting open problem is whether there exists a Type II \((24, 2^{24}, 10)\) code.

A linear code, \(C\), over GF(4) which is self-dual with respect to the Hermitian inner product, i.e., \(u \cdot \bar{v} = 0\) for all \(u, v \in C\), is also a self-dual additive code with respect to the Hermitian trace inner product. However, most of the self-dual additive codes are not linear. Only Type II codes can be linear, since self-dual linear codes over GF(4) must contain codewords of even weight only. It follows that the set of Hermitian self-dual linear codes over GF(4) is a subset of the set of Type II self-dual additive codes over GF(4).

Example 1. The unique extremal \((6, 2^6, 4)\) code, also known as the Hexacode,
has a generator matrix
\[
\begin{pmatrix}
1 & 0 & 0 & 1 & \omega & \omega^2 \\
\omega & 0 & 0 & \omega & 1 & \omega^2 \\
0 & 1 & 0 & \omega & 1 & \omega \\
0 & \omega & 0 & \omega^2 & \omega^2 & 1 \\
0 & 0 & 1 & \omega & \omega & 1 \\
0 & 0 & \omega & \omega^2 & \omega^2 & \omega
\end{pmatrix}.
\]

This code has weight enumerator \(W(x, y) = x^6 + 45x^2y^4 + 18y^6\). It is therefore of Type II, and it can be verified that it is also a linear code.

Two self-dual additive codes over GF(4), \(C\) and \(C'\), are equivalent if and only if the codewords of \(C\) can be mapped onto the codewords of \(C'\) by a map that preserves self-duality. Such a map must consist of a permutation of coordinates (columns of the generator matrix), followed by multiplication of coordinates by nonzero elements from GF(4), followed by possible conjugation of coordinates. For a code of length \(n\), there is a total of \(6^n n!\) such maps. The 6 possible transformations given by scaling and conjugation of a coordinate are equivalent to the 6 permutations of the elements \(\{1, \omega, \omega^2\}\) in the coordinate. A map that maps \(C\) to \(C'\) is called an automorphism of \(C\). All automorphisms of \(C\) make up an automorphism group, denoted \(\text{Aut}(C)\). The number of distinct codes equivalent to \(C\) is then given by \(\frac{6^n n!}{|\text{Aut}(C)|}\). By summing the sizes of all equivalence classes, we find the total number of distinct codes of length \(n\), denoted \(T_n\). It was shown by Hohn [16] that \(T_n\) is also given by the mass formula,

\[
T_n = \prod_{i=1}^{n} (2^i + 1) = \sum_{j=1}^{t_n} \frac{6^n n!}{|\text{Aut}(C_j)|},
\]

where the sum is over all equivalence classes. Similarly, the total number of distinct Type II codes of length \(n\) is given by

\[
T_{II}^n = \prod_{i=0}^{n-1} (2^i + 1) = \sum_{j=1}^{t_{II}} \frac{6^n n!}{|\text{Aut}(C_j)|},
\]

where the sum is over the equivalence classes of Type II codes. By assuming that \(|\text{Aut}(C_j)| = 1\) for all \(j\) in Eq. (5), we get a lower bound on \(t_n\), the number of inequivalent codes of length \(n\).

\[
t_n \geq \left\lceil \prod_{i=1}^{n} (2^i + 1) \right\rceil \frac{6^n n!}{|\text{Aut}(C)|}
\]

A similar bound on \(t_{II}^n\) can be derived from Eq. (6).

We can use the computational algebra system Magma [5] to find the automorphism group of a code. Since, at this time, Magma has no explicit function for calculating the automorphism group of an additive code, we use the following method, described by Calderbank et al. [4]. We map the \((n, 2^k)\) additive code \(C\) over GF(4) to the \([3n, k]\) binary linear code \(\beta(C)\) by applying the map \(0 \mapsto 000, 1 \mapsto 011, \omega \mapsto 101, \omega^2 \mapsto 110\) to each generator of \(C\). We then use Magma to find \(\text{Aut}(\beta(C)) \cap \text{Aut}(\beta(\text{GF}(4)^n))\), which will be isomorphic to \(\text{Aut}(C)\).

If we are given \(t_n\) inequivalent codes of length \(n\), i.e., one code from each equivalence class, it is relatively easy to calculate the automorphism group size.
of each code, as described above, and verify that the mass formula defined by
Eq. 3 gives the correct value. But to actually find a set of \(t_n\) inequivalent codes,
or just the value of \(t_n\), is a hard problem. All self-dual additive codes over \(GF(4)\)
of length \(n\) were first classified, up to equivalence, by Calderbank et al. 4 for
\(n \leq 5\) and by Hohn 10 for \(n \leq 7\). Hohn also classified all Type II codes of
length 8. Using a different terminology, the codes of length \(n\) were implicitly
classified by Hein, Eisert, and Briegel 14 for \(n \leq 7\) and by Glynn et al. 12 for
\(n \leq 9\). These classifications were not verified using the mass formula defined
by Eq. 4. Gaborit et al. 8, 10 have classified all extremal codes of length 8,
9, and 11, and all extremal Type II codes of length 12. Bachoc and Gabo-
rit 1 classified all extremal Type II codes of length 10, and they also showed that
there are at least 490 extremal Type II codes of length 14 and gave a partial
result on the unicity of the extremal Type II code of length 18. A review of
the current status of the classification of various types of self-dual codes is given by
Huffman 13.

In this paper, we will give a complete classification of all codes of length up
to 12, and all extremal Type II codes of length 14. But first, in Section 2 we
introduce isotropic systems and show that they correspond to self-dual additive
codes over \(GF(4)\). It is known that isotropic systems can be represented by
graphs. In Section 3 we define graph codes. Theorem 6 shows that every code
can be represented by a graph. This gives us a much smaller set of objects to
work with. In Section 4 we introduce local complementation, and Theorem 12
states that two codes are equivalent if and only if the corresponding graphs
are related via local complementations and graph isomorphism. This implies
that classifying codes up to equivalence is essentially the same as classifying
orbits of graphs under local complementation. We describe an algorithm for
generating such graph orbits in Section 5. This algorithm was used to classify
all codes of length up to 12. We show that Type II codes correspond to a special
class of graphs and use this fact to classify all extremal Type II codes of length
14. Finally, we determine that the smallest Type I and Type II codes with
trivial automorphism group have length 9 and 12, respectively. In Section 6 we
conclude and mention some other results.

2 Isotropic Systems

We define a mapping \(\phi : GF(4) \rightarrow GF(2)^2\) by \(\phi(x) = (Tr(xω^2), Tr(x))\), i.e.,
\(0 \mapsto (0,0), 1 \mapsto (1,0), ω \mapsto (0,1)\) and \(ω^2 \mapsto (1,1)\). The reverse mapping
\(\phi^{-1} : GF(2)^2 \rightarrow GF(4)\) is given by \(\phi^{-1}(a,b) = a + ωb\). Let \(u \in GF(2)^{2n}\) be writ-
ten as \(u = (a|b) = (a_1, a_2, \ldots, a_n, b_1, b_2, \ldots, b_n)\). We extend the mapping \(\phi : GF(4)^n \rightarrow GF(2)^{2n}\) by letting \(\phi(v) = (a|b)\) where \(\phi(v_i) = (a_i, b_i)\). Likewise, we
define \(\phi^{-1} : GF(2)^{2n} \rightarrow GF(4)^n\) by \(\phi^{-1}(a|b) = a + ωb\). We define the symplectic
inner product of \((a|b), (a'|b')\) \(\in GF(2)^{2n}\) as \(\langle (a|b), (a'|b') \rangle = a \cdot b' + b \cdot a'\). A
subset \(I \subset GF(2)^{2n}\) is called totally isotropic if \(\langle u, v \rangle = 0\) for all \(u, v \in I\).

Definition 2. A totally isotropic linear subspace of \(GF(2)^{2n}\) with dimension \(n\)
defines an isotropic system 2. An isotropic system can therefore be defined by
the row space of a full rank \(n \times 2n\) binary matrix \((A|B)\), where \(AB^T + BA^T = 0\).

Theorem 3. Every self-dual additive code over \(GF(4)\) can be uniquely repre-
sentated as an isotropic system, and every isotropic system can be uniquely
represented as a self-dual additive code over GF(4).

Proof. Let \( C \subseteq GF(4)^n \) be a self-dual additive code. Map \( C \) to \( \mathcal{I} \subseteq GF(2)^{2n} \) by mapping each codeword \( u \in C \) to \( \phi(u) = (a|b) \in GF(2)^{2n} \). \( \mathcal{I} \) must then be a linear subspace of \( GF(2)^{2n} \) with dimension \( n \). \( (a|b), (a'|b') \in \mathcal{I} \) are orthogonal with respect to the symplectic inner product if and only if \( \phi^{-1}(a|b), \phi^{-1}(a'|b') \in C \) are orthogonal with respect to the Hermitian trace inner product, because

\[
\phi^{-1}(a|b) \ast \phi^{-1}(a'|b') = \text{Tr}(\phi^{-1}(a|b) \cdot \phi^{-1}(a'|b')) = \text{Tr}((a + \omega b) \cdot (a' + \omega b')) = (a \cdot a') \text{Tr}(1) + (a \cdot b') \text{Tr}(\omega) + (b \cdot a') \text{Tr}(\omega) + (b \cdot b') \text{Tr}(1) = a \cdot b' + b \cdot a'.
\]

Since \( C \) is self-dual, \( u \ast v = 0 \) for all \( u, v \in C \), and \( \mathcal{I} \) must therefore be totally isotropic. It follows that \( \mathcal{I} \) defines an isotropic system. Likewise, the reverse mapping from an isotropic system to a subset of \( GF(4)^n \) will always give a self-dual additive code over \( GF(4) \).

Example 4. The row-space of \((A|B)\) defines an isotropic system, while \( C = A + \omega B \) is a generator matrix of the \((6, 2^6, 4)\) Hexacode.

\[
(A|B) = \begin{pmatrix}
1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\
0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 1 & 1 \\
0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 1 \\
0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 1 & 0 \\
0 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 1 & 1 \\
\end{pmatrix}
\]

\[
C = \begin{pmatrix}
1 & 0 & 0 & 1 & \omega & \omega \\
\omega & 0 & 0 & \omega & \omega^2 & \omega \\
0 & 1 & 0 & \omega & 1 & \omega \\
0 & \omega & 0 & \omega^2 & \omega & \omega^2 \\
0 & 0 & 1 & \omega & 1 & \omega \\
0 & 0 & \omega & \omega^2 & \omega^2 & \omega \\
\end{pmatrix}
\]

3 Graph Representation

A graph is a pair \( G = (V, E) \) where \( V \) is a set of vertices, and \( E \subseteq V \times V \) is a set of edges. A graph with \( n \) vertices can be represented by an \( n \times n \) adjacency matrix \( \Gamma \), where \( \gamma_{ij} = 1 \) if \( \{i, j\} \in E \), and \( \gamma_{ij} = 0 \) otherwise. We will only consider simple undirected graphs whose adjacency matrices are symmetric with all diagonal elements being 0. The neighbourhood of \( v \in V \), denoted \( N_v \subseteq V \), is the set of vertices connected to \( v \) by an edge. The number of vertices adjacent to \( v \), \( |N_v| \), is called the degree of \( v \). The induced subgraph of \( G \) on \( W \subseteq V \) contains vertices \( W \) and all edges from \( E \) whose endpoints are both in \( W \). The complement of \( G \) is found by replacing \( E \) with \( V \times V - E \), i.e., the edges in \( E \) are changed to non-edges, and the non-edges to edges. Two graphs \( G = (V, E) \) and \( G' = (V, E') \) are isomorphic if and only if there exists a permutation \( \pi \) of \( V \) such that \( \{u, v\} \in E \iff \{\pi(u), \pi(v)\} \in E' \). A path is a sequence of vertices, \((v_1, v_2, \ldots, v_l)\), such that \( \{v_1, v_2\}, \{v_2, v_3\}, \ldots, \{v_{l-1}, v_l\} \in E \). A graph is connected if there is a path from any vertex to any other vertex in the graph.

Definition 5. A graph code is an additive code over GF(4) that has a generator matrix of the form \( C = \Gamma + \omega I \), where \( I \) is the identity matrix and \( \Gamma \) is the adjacency matrix of a simple undirected graph.
A graph code is always self-dual, since its generator matrix has full rank over 
\( \text{GF}(2) \) and \( C C^T \) only contains entries from \( \text{GF}(2) \) whose traces must be zero. 
This construction for self-dual additive codes over \( \text{GF}(4) \) has also been used by 
Tonchev \[23\].

**Theorem 6.** Every self-dual additive code over \( \text{GF}(4) \) is equivalent to a graph code.

**Proof.** (This proof is due to Van den Nest, Dehaene, and De Moor \[22, 20\].) 
We recall that the generator matrix of a self-dual additive code over \( \text{GF}(4) \) 
corresponds to an \( n \times 2n \) binary matrix \( (A|B) \), such that \( C = A + \omega B \). 
The row-space of \( (A|B) \), denoted \( I \), defines an isotropic system. We must prove 
that \( I \) is also generated by \( (\Gamma|I) \), where \( I \) is the identity matrix and \( \Gamma \) is the 
adjacency matrix of a simple undirected graph.

The rows of \( (A|B) \) can be replaced by any \( n \) independent vectors from \( I \). 
This basis change can be accomplished by \( (A'|B') = M (A|B) \), where \( M \) is 
an \( n \times n \) invertible binary matrix. If \( B \) is invertible, the solution is simple, 
since \( B^{-1} (A|B) = (\Gamma|I) \). Note that \( \Gamma \) will always be a symmetric matrix, since 
\( \Gamma^T + \Gamma^T = 0 \). If the \( i \)th diagonal element of \( \Gamma \) is 1, it can be set to 0 by 
conjugating column \( i \) of \( \Gamma + \omega I \).

In the case where \( B \) has rank \( k < n \), we can perform a basis change to get 
\[
(A'|B') = \begin{pmatrix} A_1 & B_1 \\ A_2 & 0 \end{pmatrix},
\]

where \( B_1 \) is a \( k \times n \) matrix with full rank, and \( A_1 \) also has size \( k \times n \). Since 
the row-space of \( (A'|B') \) is totally isotropic, and \( B' \) contains an all-zero row, it must be true that 
\( A_2 B_1^T = 0 \). \( A_2 \) must have full rank, and the row space of \( B_1 \) 
must be the orthogonal complement of the row space of \( A_2 \).

We assume that \( B_1 = (B_{11}|B_{12}) \) where \( B_{11} \) is a \( k \times k \) invertible matrix. 
We also write \( A_2 = (A_{21}|A_{22}) \) where \( A_{22} \) has size \( (n-k) \times (n-k) \). Assume 
that there exists an \( x \in \text{GF}(2)^{n-k} \) such that \( A_{22} x^T = 0 \). Then the vector 
\( v = (0, \ldots, 0, x) \) of length \( n \) satisfies \( A_2 v^T = 0 \). Since the row space of \( B_1 \) is 
the orthogonal complement of the row space of \( A_2 \), we can write \( v = y B_1 \) for 
some \( y \in \text{GF}(2)^k \). We see that \( y B_{11} = 0 \), and since \( B_{11} \) has full rank, it must 
therefore be true that \( y = 0 \). This means that \( x = 0 \), which proves that \( A_{22} \) is 
an invertible matrix.

Interchanging column \( i \) of \( A' \) and column \( i \) of \( B' \) corresponds to multiplication 
by \( \omega^2 \) followed by conjugation of the \( i \)th column of \( A' + \omega B' \). We can 
can therefore swap the \( i \)th columns of \( A' \) and \( B' \) for \( k < i \leq n \) to get \( (A''|B'') \). Since 
\( B_{11} \) and \( A_{22} \) are invertible, \( B'' \) must also be an invertible matrix. We then find 
\( B''^{-1} (A''|B'') = (\Gamma|I) \), and set all diagonal elements of \( \Gamma \) to 0. \( \blacksquare \)

**Example 7.** Let \( C = A + \omega B \) be the generator matrix of the \( (6, 2^6, 4) \) Hexacode 
given in Example 4. By the method described in the proof of Theorem 6, we find 
\( C' = \Gamma + \omega I \), which generates an equivalent graph code. \( \Gamma \) is the adjacency

Theorem 6 was first proved by Bouchet [3] in the context of isotropic systems, and later by Schlingemann [20] in terms of quantum stabilizer states. Proofs of Theorem 6 have also been given by Schlingemann and Werner [21], by Grassl, Klappenecker, and Rötteler [13], by Glynn et al. [11, 12], and by Van den Nest et al. [25, 26].

Swapping vertex $i$ and vertex $j$ of a graph with adjacency matrix $\Gamma$ can be accomplished by exchanging column $i$ and column $j$ of $\Gamma$ and then exchanging row $i$ and row $j$ of $\Gamma$. We call the resulting matrix $\Gamma'$. Exactly the same column and row operations map $\Gamma + \omega I$ to $\Gamma' + \omega I$. These matrices generate equivalent codes. It follows that two codes are equivalent if their corresponding graphs are isomorphic.

We have seen that every graph represents a self-dual additive code over GF(4), and that every self-dual additive code over GF(4) can be represented by a graph. It follows that we can, without loss of generality, restrict our study to codes with generator matrices of the form $\Gamma + \omega I$, where $\Gamma$ are adjacency matrices of unlabeled simple undirected graphs.
4 Local Complementation

Definition 8. Given a graph \( G = (V, E) \) and a vertex \( v \in V \), let \( N_v \subset V \) be the neighbourhood of \( v \). Local complementation (LC) on \( v \) transforms \( G \) into \( G^v \). To obtain \( G^v \), we replace the induced subgraph of \( G \) on \( N_v \) by its complement. It is easy to verify that \( (G^v)^v = G \).

Example 9. We will perform local complementation on vertex 0 of the graph \( G \), shown in Fig. 2a. We see that the neighbourhood of 0 is \( N_0 = \{1, 2, 3\} \) and that the induced subgraph on the neighbourhood has edges \( \{1, 2\} \) and \( \{1, 3\} \). The complement of this subgraph contains the single edge \( \{2, 3\} \). The resulting LC image, \( G^0 \), is seen in Fig. 2b.

Example 10. Consider the graph shown in Fig. 1a, whose corresponding graph code is the Hexacode. An LC operation on any vertex of this graph produces the graph shown in Fig. 1b. An LC operation on the vertex in the centre of the graph shown in Fig. 1b gives the same graph, up to isomorphism. LC operations on any of the other five vertices produces the graph shown in Fig. 1a.

Theorem 11. Let \( \Gamma \) be the adjacency matrix of the graph \( G = (V, E) \), and \( \Gamma^v \) be the adjacency matrix of \( G^v \), for any \( v \in V \). The codes generated by \( C = \Gamma + \omega I \) and \( C' = \Gamma^v + \omega I \) are equivalent.

Proof. We show that \( C \) can be transformed into \( C' \) by using only operations that map a code to an equivalent code. Each row and each column of \( C \) correspond to a vertex in \( V \). Let \( N_v \) denote the neighbourhood of \( v \). For all \( i \in N_v \), add row \( v \) of \( C \) to row \( i \) of \( C \). Multiply column \( v \) of \( C \) by \( \omega \) and then conjugate the same column. Finally, conjugate column \( i \) of \( C \), for all \( i \in N_v \). The resulting matrix is \( C' \).

Theorem 12. Two self-dual additive codes over GF(4), \( C \) and \( C' \), with graph representations \( G \) and \( G' \), are equivalent if and only if there is a finite sequence of not necessarily distinct vertices \( (v_1, v_2, \ldots, v_n) \), such that \( ((G^{v_1})^{v_2} \ldots)^{v_n} \) is isomorphic to \( G' \).

Sketch of proof. Let \( \Gamma \) be the adjacency matrix of \( G \), and let \( C_G \) be the code generated by \( \Gamma + \omega I \). Likewise, let \( \Gamma' \) be the adjacency matrix of \( G' \), and let \( C_G' \) be the code generated by \( \Gamma' + \omega I \). If the codewords of \( C \) are mapped onto the codewords of \( C' \) by one of the \( 6^n n! \) combinations of coordinate permutations, coordinate scalings, and coordinate conjugations, then there must also be a
transformation from this set that maps the codewords of $C_G$ onto the codewords of $C'_G$. Consequently, we only need to consider those transformations that map a graph code to another graph code. The codes obtained by the $n!$ possible permutations of coordinates correspond to graph isomorphisms.

Let $C = \Gamma + \omega I$ be transformed into $C' = A + \omega B$ by coordinate scalings and conjugations. Then $C'$ is a graph code if and only if $B$ is invertible and all diagonal elements of $B^{-1}A$ are zero. It is easy to verify that conjugation of column $i$ of $C'$ has no effect on $B$, but flips the value of the $i$th diagonal element of $B^{-1}A$. Given a combination of column scalings on $C$ such that the resulting $B$ is invertible, there must therefore be a unique combination of column conjugations on $C$ such that the resulting $B^{-1}A$ has zero diagonal. We must therefore show that any combination of column scalings on $C$ that give an invertible $B$ can be performed by a sequence of LC operations on $G$.

Multiplying column $i$ of $C$ by $\omega^2$ replaces column $i$ of $I$ with column $i$ of $\Gamma$. Multiplying column $i$ of $C$ by $\omega$ adds column $i$ of $\Gamma$ to column $i$ of $I$. It is then possible to show which of the $3^n$ possible scalings do not give an invertible $B$. A vertex $v$ of $G$ corresponds to a column of $\Gamma$. The neighbourhood of $v$, $N_v$, corresponds to a set of columns of $\Gamma$. We know from Theorem 11 that an LC operation on vertex $i$ of $G$ corresponds to a scaling of column $i$ of $C$ by $\omega$ followed by conjugation of column $i$ and all columns in $N_i$. Observe that conjugating a coordinate followed by a scaling by $\omega$ is equivalent to scaling by $\omega^2$ followed by conjugation. Note in particular that the local complementations $((G_i)^j)^i$, where $i$ and $j$ are adjacent vertices, are equivalent to scaling both column $i$ and column $j$ of $C$ by $\omega^2$. It can be verified that any combination of column scalings that map a graph code to a graph code can be implemented as a sequence of LC operations. The exact algorithm for finding this sequence of LC operations is quite involved, and we refer to the proof by Van den Nest et al. \[25, 26\] for the details.

Bouchet \[3\] first proved Theorem 12 in terms of isotropic systems. The same result was discovered by Van den Nest et al. \[25, 26\] in terms of quantum stabilizer states, and by Glynn et al. \[11, 12\] using finite geometry.

5 Classification

Definition 13. The \textit{LC orbit} of a graph $G$ is the set of all unlabeled graphs that can be obtained by performing any sequence of LC operations on $G$.

It follows from Theorem 12 that two self-dual additive codes over GF(4) are equivalent if and only if their graph representations are in the same LC orbit. As an example, the two graphs shown in Fig. 1a and Fig. 1b make up a complete LC orbit, and are thus the only possible graph representations of the Hexacode. The LC orbit of a graph can easily be generated by a recursive algorithm. We have used the program $\tt nauty$ \[18\] to check for graph isomorphism.

Let $G_n$ be the set of all unlabeled simple undirected connected graphs on $n$ vertices. Connected graphs correspond to \textit{indecomposable} codes. A code is decomposable if it can be written as the direct sum of two smaller codes. For example, let $C$ be an $(n, 2^n, d)$ code and $C'$ an $(n', 2^{n'}, d')$ code. The direct sum, $C \oplus C' = \{u||v | u \in C, v \in C'\}$, where $||$ means concatenation, is an $(n + n', 2^{n+n'}, \min\{d, d'\})$ code. It follows that all decomposable codes of
length $n$ can be classified easily once all indecomposable codes of length less than $n$ are known.

The set of all distinct LC orbits of connected graphs on $n$ vertices is a partitioning of $G_n$ into $i_n$ disjoint sets. $i_n$ is also the number of indecomposable self-dual additive codes over GF(4) of length $n$, up to equivalence. Let $L_n$ be a set containing one representative from each LC orbit of connected graphs on $n$ vertices. We have devised several algorithms [7] for finding such sets of representatives. The simplest approach is to start with the set $G_n$ and generate LC orbits of its members until we have a partitioning of $G_n$. The following more efficient technique was described by Glynn et al. [12]. Let the $2^n - 1$ extensions of a graph on $n$ vertices be formed by adding a new vertex and joining it to all possible combinations of at least one of the old vertices. The set $E_n$, containing $i_n - 1(2^n - 1)$ graphs, is formed by making all possible extensions of all graphs in $L_{n-1}$.

**Theorem 14.** $L_n \subset E_n$, i.e., the set $E_n$ will contain at least one representative from each LC orbit of connected graphs on $n$ vertices.

**Proof.** Let $G = (V, E) \in G_n$, and choose any subset $W \subset V$ of $n-1$ vertices. By doing LC operations on vertices in $W$, we can transform the induced subgraph of $G$ on $W$ into one of the graphs in $L_{n-1}$ that were extended when $E_n$ was constructed. It follows that for all $G \in G_n$, some graph in the LC orbit of $G$ must be part of $E_n$. The set $E_n$ will be much smaller than $G_n$, so it will be more efficient to search for a set of LC orbit representatives within $E_n$. It is also desirable to partition the set $E_n$ such that graphs from two different partitions are guaranteed to belong to different LC orbits. We can then consider each partition independently, which reduces the amount of memory required and allow for parallel processing. To do this, we must have some property that is invariant over the LC orbit and that can be calculated quickly.

The special form of the generator matrix of a graph code makes it easier to find the number of codewords of weight $i < n$. If $C$ is generated by $C = \Gamma + \omega I$, then any codeword formed by adding $i$ rows of $C$ must have weight at least $i$. This means that we can find the partial weight distribution of $C$, $(A_0, A_1, \ldots, A_j)$, for some $j < n$, by only considering codewords formed by adding $j$ or fewer rows of $C$. We calculate the partial weight distribution, for a suitable choice of $j$, of all codes corresponding to graphs in $E_n$. Codes with different partial weight distribution can never be equivalent, so we partition $E_n$ such that graphs corresponding to codes with the same partial weight distribution are always in the same partition.

Using the described techniques, and a parallel cluster computer, we were able to classify all self-dual additive codes over GF(4) of length up to 12. The results have been verified by checking that the sizes of all LC orbits add up to the number of graphs in $G_n$. The sizes of the automorphism groups of all codes have also been calculated, and it has been verified that that the mass formulas defined by Eq. (5) and Eq. (6) give the correct values. Table II gives the values of $i_n$, the number of distinct LC orbits of connected graphs on $n$ vertices, which is also the number of inequivalent indecomposable codes of length $n$. The table also gives the values of $i_n^{II}$, the number of indecomposable Type II codes. The total number of inequivalent codes of length $n$, $t_n$, and the total number of
Type II codes of length $n$, $i_{n}^{I}$, are shown in Table 2. The numbers $t_n$ are easily derived from the numbers $i_n$ by using the Euler transform \[ c_n = \sum_{d|n} d_i d \]

$$
t_1 = c_1
$$

$$
t_n = \frac{1}{n} \left( c_n + \sum_{k=1}^{n-1} c_k t_{n-k} \right).
$$

The numbers $i_{n}^{II}$ are similarly derived from $i_{n}^{I}$. The values of $i_n$ and $t_n$ can be found as sequences A090899 and A094927 in The On-Line Encyclopedia of Integer Sequences 23. Table 3 and Table 4 list by minimum distance the numbers of indecomposable codes and the total numbers of codes. 1 Table 5 and Table 6 similarly list the numbers of Type II codes by minimum distance. The numbers of Type I codes can be obtained by subtracting the numbers of Type II codes from the total numbers. The number of distinct weight enumerators of all codes of length $n$ and minimum distance $d$ can be found in Table 7. There are obviously too many codes to give a complete list here, but a database containing one representative from each equivalence class, with information about weight enumerators, automorphism groups, etc., is available on-line \[24\].

Our results give a complete classification of the extremal Type I $(10,2^{10},4)$ and $(12,2^{12},5)$ codes. These classifications were previously unknown. The 101 extremal Type I $(10,2^{10},4)$ codes have 6 distinct weight enumerators, $W_{10,1}(x,y) = x^{10} + 10x^{6}y^{4} + 72x^{5}y^{5} + 160x^{4}y^{6} + 240x^{3}y^{7} + 285x^{2}y^{8} + 200xy^{9} + 56y^{10}$, $W_{10,2}(x,y) = x^{10} + 14x^{6}y^{4} + 64x^{5}y^{5} + 156x^{4}y^{6} + 256x^{3}y^{7} + 281x^{2}y^{8} + 192xy^{9} + 60y^{10}$, $W_{10,3}(x,y) = x^{10} + 18x^{6}y^{4} + 56x^{5}y^{5} + 152x^{4}y^{6} + 272x^{3}y^{7} + 277x^{2}y^{8} + 184xy^{9} + 64y^{10}$, $W_{10,4}(x,y) = x^{10} + 22x^{6}y^{4} + 48x^{5}y^{5} + 148x^{4}y^{6} + 288x^{3}y^{7} + 273x^{2}y^{8} + 176xy^{9} + 68y^{10}$, $W_{10,5}(x,y) = x^{10} + 26x^{6}y^{4} + 40x^{5}y^{5} + 144x^{4}y^{6} + 304x^{3}y^{7} + 260x^{2}y^{8} + 168xy^{9} + 72y^{10}$, $W_{10,6}(x,y) = x^{10} + 30x^{6}y^{4} + 32x^{5}y^{5} + 140x^{4}y^{6} + 320x^{3}y^{7} + 265x^{2}y^{8} + 160xy^{9} + 76y^{10}$.

Table 5 lists the number of such codes by weight enumerator and automorphism group size. The 63 extremal Type I $(12,2^{12},5)$ codes have 2 distinct weight

Note that some authors 22, 23 give 3 as the total number of self-dual $(7,2^7,3)$ codes. The correct number is 4.

All \( d \) enumerators,

\[
W_{12,1}(x, y) = x^{12} + 40x^7y^5 + 212x^6y^6 + 424x^5y^7 + 725x^4y^8 + 1080x^3y^9 + 980x^2y^{10} + 504xy^{11} + 130y^{12},
\]

\[
W_{12,2}(x, y) = x^{12} + 48x^7y^5 + 188x^6y^6 + 432x^5y^7 + 765x^4y^8 + 1040x^3y^9 + 972x^2y^{10} + 528xy^{11} + 122y^{12}.
\]

Table lists the number of such codes by weight enumerator and automorphism group size.

By observing that graphs corresponding to Type II codes have a special property, we are able to extend our classification to all the 1,020 extremal Type II \((14, 2^{14}, 6)\) codes. It was previously shown by Bachoc and Gaborit \[1\] that there are at least 490 such codes.

**Theorem 15.** Let \( \Gamma \) be the adjacency matrix of the graph \( G \). The code \( C \) generated by \( C = \Gamma + \omega I \) is of Type II if and only if \( G \) is anti-Eulerian, i.e., if all its vertices have odd degree.

**Proof.** If \( C \) is of Type II, then every row of \( C \) must have even weight. It follows that every row of \( \Gamma \) must have odd weight, and therefore correspond to an anti-Eulerian graph. Conversely, if all rows of \( C \) have even weight, \( C \) must be of Type II, since the codeword formed by adding any subset of these rows must also have even weight. This follows from the fact that for any two codewords of a self-dual code, there must be an even number of coordinates where the codewords have different non-zero values.

An anti-Eulerian graph is the complement of an Eulerian graph, i.e., a graph where all vertices have even degree. It is easy to show that all anti-Eulerian graphs must have an even number of vertices, and it follows that all Type II codes must have even length. To classify Type II codes of length 14, we proceed as follows. We take the set \( L_{12} \) containing 1,274,068 LC orbit representatives of graphs on 12 vertices. All these graphs are then extended, but in a slightly different way than earlier. To each graph we add one vertex and join it to all possible combinations of at least one of the old vertices. To each obtained graph we then add a second vertex and join it to those of the 13 other vertices that have even degree. (If the result is not a connected anti-Eulerian graph, it is rejected.) By an argument similar to Theorem 14, it can be shown that all
Table 8: Number of Extremal Type I $(10, 2^{10}, 4)$ Codes with Weight Enumerator $w$ and Automorphism Group of Size $a$

| $a \backslash w$ | $W_{10,1}$ | $W_{10,2}$ | $W_{10,3}$ | $W_{10,4}$ | $W_{10,5}$ | $W_{10,6}$ | All |

All graphs corresponding to Type II codes of length 14 must be part of this extended set. Classifying all Type II codes of length 14 turned out to be infeasible with our computational resources. Even when using partitioning by partial weight distribution, the largest partitions were too large to be processed. However, we were able to generate the LC orbits of all graphs corresponding to $(14, 2^{14}, 6)$ codes. Extremal Type II codes have a unique weight enumerator, and the weight enumerator of a $(14, 2^{14}, 6)$ code must be

$$W_{14}(x, y) = x^{14} + 273x^8y^6 + 2457x^6y^8 + 7098x^4y^{10} + 6006x^2y^{12} + 549y^{14}.$$  

Table 10 lists the number of codes by automorphism group size. Note that codes with 21, 168, and 2184 automorphisms were previously unknown. Generator matrices of the codes are available on-line [6].

As mentioned before, the set of self-dual linear codes over GF(4) is a subset of the self-dual additive codes of Type II. Note that conjugation of single coordinates does not preserve the linearity of a code. It was shown by Van den Nest [25] that the code $C$ generated by a matrix of the form $\Gamma + \omega I$ can not be linear. However, if there is a linear code equivalent to $C$, it can be found by conjugating some coordinates. Conjugating coordinates of $C$ is equivalent to setting some diagonal elements of $\Gamma$ to 1. Let $A$ be a binary diagonal matrix such that $\Gamma + A + \omega I$ generates a linear code. Van den Nest [25] proved that $C$ is equivalent to a linear code if and only if there exists such a matrix $A$ that satisfies $\Gamma^2 + A\Gamma + \Gamma A + \Gamma + I = 0$. A similar result was found by Glynn et al. [12]. Using this method, it is easy to check whether the LC orbit of a given graph corresponds to a linear code. However, self-dual linear codes over GF(4) have already been classified up to length 16, and we have not found a way to extend this result using the graph approach.
We remark that if $C$ is a self-dual additive code over $GF(4)$ with generator matrix $\Gamma + \omega I$, it can be shown that the additive code over $\mathbb{Z}_4$ generated by $2\Gamma + I$ has the same weight distribution as $C$. It has also been shown \[10\] that self-dual additive codes over $GF(4)$ can be mapped to isodual binary linear codes, i.e., codes that are equivalent to their duals, by the mapping $0 \mapsto 00$, $1 \mapsto 11$, $\omega \mapsto 01$ and $\omega^2 \mapsto 10$. A code over $\mathbb{Z}_4$ and a binary code obtained from the same self-dual additive code over $GF(4)$ by these two methods are related by the well-known Gray map. There are also several mappings from self-dual additive codes over $GF(4)$ to self-dual and self-orthogonal binary linear codes \[10, 16, 17\].

An interesting problem, posed by Höhn \[16\], is to find the smallest code with trivial automorphism group, i.e., automorphism group of size 1. We find that there is no such code of length up to 8, but there is a single code of length 9 with trivial automorphism group. This code has generator matrix

\[
\begin{pmatrix}
\omega & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\
0 & \omega & 0 & 0 & 1 & 0 & 0 & 1 \\
0 & 0 & \omega & 1 & 0 & 0 & 1 & 0 \\
0 & 0 & 1 & \omega & 0 & 0 & 0 & 1 \\
0 & 1 & 0 & 0 & \omega & 1 & 0 & 1 \\
0 & 0 & 0 & 0 & 1 & \omega & 1 & 0 \\
0 & 0 & 1 & 0 & 0 & 1 & \omega & 1 \\
1 & 1 & 0 & 1 & 0 & 0 & \omega & 0 \\
1 & 0 & 0 & 1 & 1 & 1 & 1 & \omega
\end{pmatrix}
\]

The smallest Type II codes with trivial automorphism groups have length 12. One such code is generated by

\[
\begin{pmatrix}
\omega & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 1 & 1 \\
0 & \omega & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 0 & 1 \\
0 & 0 & \omega & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 1 \\
0 & 0 & 0 & \omega & 1 & 0 & 1 & 0 & 0 & 0 & 1 \\
0 & 0 & 1 & 1 & \omega & 0 & 0 & 1 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & \omega & 0 & 0 & 1 & 1 & 1 \\
0 & 1 & 0 & 1 & 0 & 0 & \omega & 0 & 0 & 1 & 1 \\
1 & 0 & 0 & 0 & 1 & 0 & 0 & \omega & 1 & 1 & 0 \\
0 & 1 & 0 & 0 & 0 & 1 & \omega & 1 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & \omega & 1 & 0 \\
1 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 0 & \omega \\
1 & 1 & 1 & 0 & 0 & 1 & 1 & 1 & 1 & 0 & \omega
\end{pmatrix}
\]

Table \[11\] lists the numbers of Type I and Type II codes with trivial automorphism group by length and minimum distance. Note that for length 12, almost half the codes have trivial automorphism group. For high lengths, one can expect almost all codes to have trivial automorphism group \[10\]. This implies that the bound on $t_n$ given by Eq. \[8\] is tighter for higher $n$. Observe that in Table \[11\] no code of minimum distance less than 3 is listed. It is easy to show that all codes with minimum distance 1 or 2 must have nontrivial automorphisms.
Table 11: Number of Type I (Type II) Codes of Length \( n \) and Minimum Distance \( d \) with Trivial Automorphism Group

| \( d \backslash n \) | \( \leq 8 \) | 9 | 10 | 11 | 12 | 14 |
|------------------|---------|---|----|----|----|----|
| 3                | 1 (0)   | 113 (0) | 6,247 (0) | 392,649 (0) | ? (0) |
| 4                | 3 (0)   | 1,180 (0) | 163,982 (102) | ? (?) |
| 5                | 25 (0)  | ? (0) |
| 6                | ? (625) | All 0 (0) | 1 (0) | 116 (0) | 7,427 (0) | 556,656 (102) | ? (?) |

6 Conclusions

By using graph representation and equivalence via local complementation, we have classified all additive codes over GF(4) of length up to 12 that are self-dual with respect to the Hermitian trace inner product. It follows from the bound given by Eq. (7) that there are at least 72,573,549 codes of length 13. It is not feasible to classify all codes of length 13 using our method and the computational resources available to us. We were however able to classify the 1,020 extremal Type II \((14,2^{14},6)\) codes. This was done by exploiting the fact that Type II codes correspond to anti-Eulerian graphs. Finally, we showed that the smallest Type I and Type II codes with trivial automorphism group have length 9 and 12, respectively.

The graph representation of a self-dual additive code over GF(4) can also give information about the properties of the code. Tonchev [24] showed that strongly regular graphs give rise to interesting codes. In particular, codes represented by the strongly regular Paley graphs are well-known quadratic residue codes. We have shown that many extremal and optimal codes can be represented by nested regular graphs [7, 8]. Glynn et al. [12] showed that the minimum distance of a code is equal to one plus the minimum vertex degree over all graphs in the corresponding LC orbit. We have shown that the LC orbit corresponding to a code with high minimum distance only contains graphs with both small independent sets and small cliques [7, 8].

Acknowledgements We would like to thank Philippe Gaborit for his helpful comments. Also thanks to the Bergen Center for Computational Science, whose cluster computer made the results in this paper possible. This research was supported by the Research Council of Norway.
