We study the evolution of magnetic structure driven by a synthetic spin-orbit coupling in a one-dimensional two-component Bose-Hubbard model. In addition to the Mott insulator-superfluid transition, we found in Mott insulator phases a transition from a gapped ferromagnetic phase to a gapless chiral phase by increasing the strength of spin-orbit coupling. Further increasing the spin-orbit coupling drives a transition from the gapless chiral phase to a gapped antiferromagnetic phase. These magnetic structures persist in superfluid phases. In particular, in the chiral Mott insulator and chiral superfluid phases, incommensurability is observed in characteristic correlation functions. These unconventional Mott insulator phase and superfluid phase demonstrate the novel effects arising from the competition between the kinetic energy and the spin-orbit coupling.

I. INTRODUCTION

Spin-orbit coupling (SOC) is known to play an important role for many exotic phenomena in condensed matter physics, such as topological insulators,\(^7\,8\) topological superconductivity,\(^9\,10\) and unconventional magnetism.\(^11\) Example materials include HgCdTe quantum wells,\(^12\,13\) Copper Benzoate,\(^14\,15\) and Skyrmion phases. More recently, unconventional Mott insulator phase and superfluid phase demonstrate the novel effects arising from the competition between the kinetic energy and the spin-orbit coupling in both ultracold atomic systems and condensed matter physics.

Up to now, whereas most experimental and theoretical studies on the SOC mainly focus on continuous systems,\(^13\,24\) some experimentalists and theorists recently turn to study related phenomena in optical lattices. On one hand, lattices are the basic structure in solid state physics and optical lattices are the key for simulating condensed matter physics\(^25\,26\) in ultracold atomic setups. On the other hand, the advantage of lattice systems over continuum is that a variety of analytical and numerical methods for studying strongly correlated systems have been well established in the past several decades. For examples, theoretical works based on spin wave, slave boson and Monte Carlo have predicted a rich zero-temperature magnetic phase diagram\(^27\,28\) for two-dimensional bosonic systems with Rashba SOC in the Mott region. It includes ferromagnetic (FM), antiferromagnetic (AF), spiral, vortex and Skyrmion phases. More recently, unconventional superfluid (SF) phases have been found\(^29\,30\) in the Bose-Hubbard model with various types of SOC in two dimensions. These results are in contrast to the relatively simple Mott insulator (MI) and SF phases for the two-component Bose-Hubbard model\(^31\) without the SOC. In addition, fermionic lattice models with the Rashba SOC recently also become the context of theoretical investigations of some intriguing effects in various geometries such as ladders\(^32\) and square lattice.\(^33\)

In spite of those theoretical great interests in the Rashba SOC recently,\(^34\,35\) there is no experimental realization of such a SOC in ultracold atomic systems so far. Therefore, in this paper we focus on the SOC that has already been realized in ultracold atom experiments,
which is proportional to $p_x \sigma_y$. Since this SOC is along one spatial direction and of abelian nature, it is natural to start our study on the effects of the SOC from a one-dimensional model. In the tight-binding form, Hamiltonian including the kinetic energy and the SOC can be generally written as

$$\mathcal{H}_\text{t} = -t \sum_{\tau} (\hat{c}_{i\tau}^\dagger \hat{c}_{i+1\tau} + h.c.) + \mathcal{T}_\text{soc}$$

where $\hat{c}_{i\tau}$ ($\hat{c}_{i\tau}^\dagger$) denotes the annihilation (creation) operators at site $i$ for spin $\tau$. $\tau$ takes $\uparrow$ and $\downarrow$, representing two internal states of atoms. The first term in Eq. (1) is the kinetic energy and $t$ is the hopping matrix between nearest neighbor sites. $\mathcal{T}_\text{soc}$ describes the SOC realized in experiments. Its tight-binding form is represented by

$$\mathcal{T}_\text{soc} = -\lambda \sum_{i} (\hat{c}_{i\uparrow}^\dagger \hat{c}_{i+1\uparrow} - \hat{c}_{i\downarrow}^\dagger \hat{c}_{i+1\downarrow}) + h.c.,$$

with $\lambda$ being a SOC strength.

It turns out that $\mathcal{T}_\text{soc}$ can be eliminated by a site-dependent rotation in its internal space of each site, resulting in a renormalization of the hopping integral $t$. To show this, we take the following rotation $^{27,38}$ around $y$-axis at site $i$,

$$\begin{pmatrix} \hat{c}_{i\uparrow} \\ \hat{c}_{i\downarrow} \end{pmatrix} \rightarrow \begin{pmatrix} \cos \frac{\pi \eta}{4} & -\sin \frac{\pi \eta}{4} \\ \sin \frac{\pi \eta}{4} & \cos \frac{\pi \eta}{4} \end{pmatrix} \begin{pmatrix} \hat{c}_{i\uparrow}^\dagger \\ \hat{c}_{i\downarrow}^\dagger \end{pmatrix}. \quad (3)$$

By substituting Eq. (3) into Eq. (1) and setting $\omega_{i+1} - \omega_i = 2 \arctan(\frac{1}{2})$, one finds that $\mathcal{T}_\text{soc}$ disappears with $t$ renormalized to $\sqrt{t^2 + \lambda^2}$. However, a realistic Hamiltonian inevitably involves some other terms such as interactions for correlations or a Zeeman term for experiments, which we denote as $\mathcal{H}_\text{other}$. If $\mathcal{H}_\text{other}$ is invariant under the rotation, the net effect of SOC is merely renormalizing the hopping term and considered to be trivial in this case. The situation can be easily altered by introducing an (artificial) Zeeman field into $\mathcal{H}_\text{other}$. In this case, the SOC becomes relevant and new physical phenomena are expected to occur. In particular, in the presence of both the SOC and Zeeman field, a variety of exotic phases such as topological superconductivity have been proposed $^{39-42}$ in fermion systems.

Zeeman field definitely breaks the time-reversal symmetry and the polarization strongly depends on the direction of the Zeeman field. Instead, in our work, we consider an experimentally relevant model without breaking time-reversal symmetry, i.e. a two-component Bose-Hubbard model with SOC, which reads

$$\mathcal{H} = \mathcal{H}_\text{t} + \frac{U}{2} \sum_{\tau} \hat{n}_{i\tau} (\hat{n}_{i\tau} - 1) + U' \sum_{\tau} \hat{n}_{i\tau} \hat{n}_{i\tau}$$

$$-\mu \sum_{i} (\hat{n}_{i\uparrow} + \hat{n}_{i\downarrow}),$$

where $\mathcal{H}_\text{t}$ is the same as Hamiltonian (1) but $\hat{c}_{i\tau}$, $\hat{c}_{i\tau}^\dagger$ is restricted for bosons here. $U$ is on-site intracomponent interaction and $U'$ is the intercomponent one. $\hat{n}_{i\tau} = \hat{c}_{i\tau}^\dagger \hat{c}_{i\tau}$ is the boson number operator with spin $\tau$ at site $i$, $\mu$ is the chemical potential to control the filling factor. When $U' = U$, the interaction part is invariant under the rotation $^{43}$. Therefore, $\mathcal{T}_\text{soc}$ can be eliminated, resulting in a standard two-component Bose-Hubbard model (TBHM), which has been extensively studied in literature $^{34,43-45}$. However, when $U' \neq U$, the interaction part is not invariant any more under the rotation $^{43}$. One can then expect that some new phenomena would emerge. For example, spontaneous $Z_2$ symmetry breaking resulting from the competition between the kinetic energy and SOC has been predicted $^{44}$ for $U' < U$.

We recall that Hamiltonian (1) has a $U(1) \times Z_2$ symmetry, described by the transformation

$$\hat{c}_{i\tau} \rightarrow \sum_{\tau} \left[ e^{i\phi} e^{-i\pi \sigma_y / 2} \right]_{\tau,\tau} \hat{c}_{i\tau},$$

which indicates that only the total particle number is conserved. Moreover, Hamiltonian (1) is unchanged by interchanging $t$ and $\lambda$ with the following transformation

$$\hat{c}_{i\tau} \rightarrow \text{sign}_\tau \hat{c}_{i\tau}, \quad \hat{c}_{i+1\tau} \rightarrow \hat{c}_{i+1\tau}, \quad \hat{c}_{i+2\tau} \rightarrow -\text{sign}_\tau \hat{c}_{i+2\tau}, \quad \hat{c}_{i+3\tau} \rightarrow -\hat{c}_{i+3\tau}$$

for every 4-sites with sign$_\tau = 1$ and sign$_\tau = -1$ and $\tau$ represents the opposite spin of $\tau$. These symmetries would be helpful for understanding the properties of Hamiltonian (1). Particularly, we can define the ratio

$$\eta = \lambda / (t + \lambda)$$

to establish a symmetric phase diagram with respect to the axis $\eta = 0.5$. The phases with $\eta \in (0.5, 1]$ can be readily figured out from those with $\eta \in [0, 0.5]$ in terms of the transformation $^{6}$.

In the absence of $\mathcal{T}_\text{soc}$, Hamiltonian (1) is reduced to the well-known TBHM. In large $U, U'$ limit and at a unit filling, it can be mapped to a spin-1/2 XXZ Heisenberg model. In particular, when $U' > U$, its ground state is in a $z$-axis Ising FM phase. Consequently, its low-energy excitation is gapful. When a small $\mathcal{T}_\text{soc}$ is set in, we would expect that its ground state remains in such a gapped FM phase. This thus greatly motivates us in this work to explore how this magnetic order evolves as the SOC increases continuously.

The rest of the paper is organized as follows: In Section II, we derive an effective magnetic Hamiltonian in large $U, U'$ limit at a unit filling. We first discuss some special cases, where the effective Hamiltonian can be simplified further so that we are able to give qualitative conclusions with available analytic results. Then we present an accurate phase diagram which is established numerically by means of the density-matrix renormalization group (DMRG) $^{44,49}$ method. In Section III, we study the transition between the MI and the SF phases, the magnetic structures as well as the momentum distribution in SF phases. Particularly, we focus on the evolution of the magnetic structure with respect to the SOC in SF phases. In Section IV, we give our conclusions.
II. EFFECTIVE MAGNETIC HAMILTONIAN IN DEEP MOTT REGION

In this section, we discuss the magnetic properties in the MI phases at the unit filling. To understand the magnetic properties of Hamiltonian \( H \), it is natural to start our discussion from the deep MI region, i.e., \( t, \lambda \ll U, U' \), where charge freedom is frozen and only spin freedom is involved at zero temperature. Under such a restriction, the low-energy behavior of Hamiltonian \( H \) can be effectively described by a spin-1/2 model. To see this, we split the Hamiltonian into two parts, \( H = H_{\text{eff}} + H_{\text{other}} \), where

\[
H_{\text{other}} = \frac{U}{2} \sum_{i} \hat{n}_{i\uparrow} (\hat{n}_{i\uparrow} - 1) + U' \sum_{i} \hat{n}_{i\uparrow} \hat{n}_{i\downarrow}.
\]

Here, \( H_{\text{other}} \) includes both the kinetic energy and the SOC and is taken as a perturbation. The ground states of \( H_{\text{other}} \) have one particle per site and is thus highly degenerate. To the second order, the effective Hamiltonian can be derived as

\[
H_{\text{eff}} = \mathcal{P} H_{\text{eff} \lambda} \left( \frac{1}{E_0} - \mathcal{P} \right) H_{\text{eff} \lambda} \mathcal{P} = \left( \frac{8 (t^2 - \lambda^2)}{-U} \right) \sum_i \hat{S}_i^z \hat{S}_{i+1}^z + \frac{4 (\lambda^2 - t^2)}{-U'} \sum_i \hat{S}_i^z \hat{S}_{i+1}^z + \frac{4 (t^2 + \lambda^2)}{-U'} \sum_i \hat{S}_i^y \hat{S}_{i+1}^y - \frac{8 \lambda t}{U} \sum_i \left( \hat{S}_i^x \hat{S}_{i+1}^x - \hat{S}_i^x \hat{S}_{i+1}^x \right)
\]

where \( \mathcal{P} \) is the projection operator onto the subspace spanned by the ground states of \( H_{\text{other}} \), \( E_0 \) is the ground state energy of \( H_{\text{other}} \), and

\[
\hat{S}_i^\nu = \sum_{\sigma, \sigma'} c_{i\sigma}^\dagger \sigma_{\tau, \tau'}^\nu \sigma_{i\tau'} \hat{c}_{i\tau'}/2
\]

are the pseudo-spin operators with \( \nu = x, y, z \) and Pauli matrix. To derive Hamiltonian \( H_0 \), we use the relations \( \hat{n}_{i\uparrow} \hat{n}_{i\downarrow} + \hat{n}_{i\downarrow} \hat{n}_{i\uparrow} = 1 \), and \( \hat{n}_{i\uparrow} \hat{n}_{i\downarrow} = 4 \hat{S}_i^z \hat{S}_{i+1}^z \). The Hamiltonian \( H_0 \) is a gapped Ising FM state with the polarization in \( z \) direction. Secondly, when \( t = 0 \), Eq. (9) has a gapped AF ground state, which is readily known through the transformation \( H_0 \). Thirdly, when \( t = \lambda \), it is in a critical phase with gapless excitations. An important implication from above analysis is that there are at least two transition points when \( \eta \) varies from 0 to 1.

To establish an accurate magnetic phase diagram, we employ the DMRG method to study the Hamiltonian \( H \). In our calculation, we take \( U \) as the energy unit and fix \( t + \lambda = 0.04U \), which well satisfy the above constraint \( t, \lambda \ll U, U' \). In Fig. 1, we show the magnetic phase diagram in \( U'/U - \eta \) plane in a deep Mott insulator region. One can see that the phase diagram consists of a gapped FM phase, a gapless chiral phase and a gapped AF phase from the bottom to the top. In both the gapped FM and the gapped AF phases, the polarization is in \( z \)-axis. The phase boundary has a reflection symmetry with respect to the axis \( \eta = 0.5 \) owing to the transformation \( H_0 \). According to our previous analysis based on the effective Hamiltonian \( H_0 \), we know that \( \eta = 0 \) corresponds to a gapped FM phase, which is in agreement with our numerical results. Such a gapped FM phase extends to a finite \( \eta_c \), with \( \eta_c \) depending monotonically on \( U'/U \). Further increasing \( \eta \) drives the ground state into a gapless chiral phase and then transits from the gapless chiral phase into a gapped AF phase at \( 1 - \eta_c \) and stays in the gapped AF phase for \( \eta \) up to 1. When \( U'/U = \infty \), \( \eta_c \) can be obtained exactly as \( \eta_c = \eta_{\infty} = 1 - \sqrt{2}/2 \). Furthermore, we found that the two phase boundaries can be well fitted by an elegant formula \( \eta = \eta_{\infty} \left( \frac{2}{\pi} \arctan \left( \frac{U' - 1}{U} \right) \right)^{\alpha} \) and \( \eta = 1 - \eta_{\infty} \left( \frac{2}{\pi} \arctan \left( \frac{U - 1}{U} \right) \right)^{\alpha} \), respectively, with \( \alpha = 1/5 \). It is worthwhile to call for analytic works, for example, by bosonization technique, to gain further insightful information related to these interesting results.

Now let us discuss the difference among these three phases in terms of spin-spin correlation functions, chiral correlation functions and excitation gaps. For simplicity, we restrict our discussion to the case \( U'/U = 1.2 \), since the results at other \( U'/U \) are found qualitatively the same. First, we found that the three phases are clearly distinguished by the spin-spin correlation functions defined as

\[
S_{ij}^\nu = \langle \psi_0 | \hat{S}_i^\nu \hat{S}_j^\nu | \psi_0 \rangle,
\]

and the corresponding static structure factors

\[
S_{ij} (q) = \frac{1}{L} \sum_{ij} e^{i \eta (i-j)} S_{ij}^\nu,
\]

where \( q \) is the momentum, \( | \psi_0 \rangle \) is the ground state of Hamiltonian \( H \) and \( L \) is the chain length. Hereafter,
FIG. 1: (Color online) Magnetic phase diagram is shown in a deep Mott region. The open circles are the phase boundary obtained by DMRG. The lower dashed line is $\eta = \eta_\infty$ and the upper dashed line is $\eta = 1 - \eta_\infty$ with $\eta_\infty = 1 - \sqrt{2}/2$, corresponding to the two critical points at $U'/U = \infty$. The red solid lines are fitting for the numerical data, given by the function $\eta = \eta_\infty \left(\frac{2}{\pi} \arctan\left(\frac{U}{U'} - 1\right)\right)^{1/5}$ for the lower boundary and $\eta = 1 - \eta_\infty \left(\frac{2}{\pi} \arctan\left(\frac{U}{U'} - 1\right)\right)^{1/5}$ for the upper boundary.

FIG. 2: (Color online) Typical static structure factors as a function of $q$ are shown (a) in the gapped FM phase at $\eta = 0.185$ and (b) in the gapless chiral phase at $\eta = 0.2$. In panel (a), $S^x(q)$ is scaled by 50 for clear vision. The chain length $L$ is 64.

FIG. 3: (Color online) Typical correlation functions $S^x_{ij}$ and $\kappa^y_{ij}$ at $t + \lambda = 0.04U$ as a function of $|i - j|$ are shown in the gapped FM phase ($\eta = 0.15$) and gapless chiral phase ($\eta = 0.5$) for $L = 128$. The red solid line in panel (a) is fitting for those data obtained by DMRG at $\eta = 0.5$ with $S^x_{ij} = 0.1614 \times \cos(|i - j|\pi/2)/|i - j|^{0.197}$. This figure clearly demonstrates the existence of long-range chiral order in the gapless chiral phase and FM order in the gapped FM phase.

our discussion on $q$-dependence of the structure factors are restricted to $q \in [0, \pi]$ since $S^y(q)$ is symmetric with respect to $q = \pi$ (and the restriction is also applied to the momentum distribution in the next section). In Fig. 2 (a), the static structure factor $S^x(q)$ and $S^z(q)$ are shown for the gapped FM phase. We found that a peak shows up at $q = 0$ in $S^z(q)$. Moreover, $S^z(0)/L$ scales to a finite value in the thermodynamic limit, indicating a long-range FM order. However, it is quite different in the gapless chiral phase. As we show in Fig. 2 (b), the peaks of both $S^x(q)$ and $S^y(q)$ are shown at the same $q$ but with $q \neq 0, \pi$, reflecting an incommensurate structure factor. This incommensurability uncovers a characteristic feature of the gapless chiral phase. Moreover, Fig. 2 indicates that a phase transition occurs between $\eta = 0.185$ and $\eta = 0.2$. In order to further illustrate different features between these two phases, we plot in Fig. 3 (a) $S^x_{ij}$ as a function of $|i - j|$ at $\eta = 0.15$ for the gapped FM phase and at $\eta = 0.5$ for the gapless chiral phase. These two values of $\eta$ are chosen a little far from the critical point to gain a clear discrimination between the two phases for the typical size we studied. As expected, $S^x_{ij}$ is finite in the large $|i - j|$ limit in the gapped FM phase, while it decays algebraically in the gapless chiral phase as a function of $|i - j|$, which can be well fitted by

$$S^x_{ij} \sim \cos(|i - j|q_s + \delta_s)/|i - j|^{\alpha_s},$$

where $q_s$, $\delta_s$ and $\alpha_s$ depend on $(t + \lambda)/U$, $\eta$, and $U'/U$. Moreover, $q_s$ just corresponds to the momentum where the peak of $S^z(q)$ locates, and depends monotonically on $\eta$. In particular, at $\eta = 0.5$, $q_s = \pi/2$, which is independent of other parameters but as an immediate consequence of the symmetry revealed by the transformation $U$. This power-law behavior of $S^x_{ij}$ is reminiscent of
Tomonaga-Luttinger liquid in the gapless chiral phase.

Second, the difference between the gapless chiral phase and other phases can be detected by chiral correlation functions, defined by

\[ \kappa_{ij}^\nu = \langle \psi_0 | (\hat{S}_i \times \hat{S}_{i+1})^\nu | \psi_0 \rangle, \nu = x, y, z. \]  

(14)

It demonstrates completely different behavior for the gapless chiral phase from the gapped FM phase as shown in Fig. 4 (b). We plot \( \kappa_{ij}^x \) as a function of \( |i-j| \) at \( \eta = 0.15 \) (for the gapped FM phase) and at \( \eta = 0.5 \) (for the gapless chiral phase). \( \kappa_{ij}^x \) is finite in the large \( |i-j| \) limit for the gapless chiral phase, indicating the existence of long-range chiral order. However, for the gapped FM phase, it is exponentially small. We also checked other \( \eta \) and confirmed that in the gapped FM phase \( \kappa_{ij}^\nu \) is always exponentially small, and in the gapless chiral phase it is always finite in the large \( |i-j| \) limit. However, near the transition point but in the gapless chiral phase, oscillation around a finite value is observed. We also calculated \( \kappa_{ij}^y, \kappa_{ij}^z \) and found that they are always exponentially small so we will not discuss them further. Our results clearly demonstrate the long-range chiral order in the gapless chiral phase.

Finally, these phases can be distinguished by a longitudinal gap, defined by

\[ \Delta_k = E_k(N, L) - E_0(N, L), \]  

(15)

where \( E_k(N, L) \) is the energy of \( k \)-th excited state with particle number \( N \) and length \( L \) and \( E_0(N, L) \) is the energy of the ground state with particle number \( N \) and length \( L \). In our work, we have to \( k = 2 \) due to the two-fold degeneracy of the ground states. In terms of these quantities defined above, the transition point from the gapped FM phase to the gapless chiral phase can be determined accurately by scanning \( \eta \). In the upper panel of Fig. 4, we show the location \( q_s \) of the peak of \( S^z(q) \) as a function of \( \eta \), and obviously a transition from the gapped FM to the gapless chiral phase occurs at \( \eta = 0.190(2) \) and the other one from the gapless chiral phase to the gapped AF phase occurs at \( \eta = 0.810(2) \). In the lower panel of Fig. 4, we show \( \Delta_2 \), which has been extrapolated to the thermodynamic limit, as a function of \( \eta \). In both the gapped FM phase and the gapped AF phase, \( \Delta_2 \) is finite, and zero otherwise in the gapless chiral phase. From the results of \( q_s \) and \( \Delta_2 \), it can be seen that the features of the gapped AF phase can be deduced from those of the gapped FM phase according to the symmetry revealed in Eq. (14) with respect to \( \eta = 0.5 \). Moreover, we note that the critical points determined from \( \Delta_2 \) are in good agreement with those given by \( q_s \), verifying that \( \Delta_2 \) and \( q_s \) together with \( \kappa_{ij}^x \) sufficiently characterize the intrinsic features for the gapless chiral phase as well as the gapped FM (AF) phase. Furthermore, these transitions are qualitatively consistent with our previous analysis based on the effective Hamiltonian (9).

III. MOTT INSULATOR-SUPERFLUID TRANSITION

In this section, we study the MI to SF transition, the magnetic structures as well as the momentum distribution in SF phases at the unit filling by DMRG.

In the left panel of Fig. 5, we show the phase diagram in \((t + \lambda) - \mu \) plane at \( \eta = 0.2, U' = 1.2U \). The phase surrounded by the curves and the \( \mu \)-axis is the MI phase, and outside is the SF phase. The upper and lower boundaries of the MI lobe are defined by the chemical potentials \( \mu^+ = E_0(N + 1, L) - E_0(N, L) \) and \( \mu^- = E_0(N, L) - E_0(N - 1, L) \) in the thermodynamic limit. The gap \( \Delta_c \) is then defined by \( \Delta_c = \mu^+ - \mu^- \). The MI phase is characterized by a finite \( \Delta_c \). At \( t + \lambda = 0 \),
Hamiltonian (4) is decoupled into a single-site one and it can be solved exactly, giving $\mu^+ = U$ and $\mu^- = 0$. For other $t + \lambda$, there is no exact solution, and thus we resort to DMRG to calculate $\mu^+$ and $\mu^-$ numerically. We can see that in the MI phase, $\Delta_0$ is obviously finite and thus the MI phase is incompressible. A reentrant behavior for MI-SF transition is observed in Fig. 5, which is typical in one dimension. We also calculated the phase diagrams at several other $\eta$, and found the curves are basically similar so we did not show them. Near the tip of the Mott lobe, the density fluctuation along a constant density line is forbidden and only phase fluctuation is allowed. Hence, we expect that such a transition is Berezinskii-Kosterlitz-Thouless(BKT) type. Following the scaling relation,

$$L\Delta_c \sim f(L/\xi)$$

where $\xi$ is the correlation length and $\xi \to \infty$ in the SF phase, we expect that $L\Delta_c$ separate for different $L$ in the MI phase but merge into one curve in the SF phase so that the emerging point gives the critical point. In the right panel, we show that the transition at the MI tip is indeed BKT type by the finite-size scaling analysis of the charge gap $\Delta_c$ with $L = 24, 32, 40, 48$ and 56. The tip of the MI lobe is estimated to be $t + \lambda \approx 0.36U$.

In Fig. 6 we have essentially shown three MI phases which actually differ from each other by three different magnetic structures. Increasing $t + \lambda$ induces a transition from MI phases to SF phases as seen from Fig. 6. It is natural to wonder whether the magnetic structures survive in the SF phases. Below we explore the magnetic structure in the SF phases in terms of correlation functions defined in Eqs. (11), (12) and (14) with DMRG calculations.

In Fig. 6 we show a typical phase diagram in $(t + \lambda) - \eta$ plane at the unit filling and $U' = 1.2U$, which includes four phases: a FM MI phase, a chiral MI phase, a FM SF phase and a chiral SF phase. The phase boundary between the SF phase and the chiral SF is determined by the peak position $q_x$ of the static structure factor defined in Eq. (12) by using the same method as we have discussed in section II. This phase diagram is plotted only for $0 \leq \eta \leq 0.5$, since the rest for $0.5 \leq \eta \leq 1$ can be obtained through the transformation. For a given $\eta$, the phase boundary between the MI and the SF phases is just the tip of a Mott lobe as we show in Fig. 6 so the corresponding transition is of BKT type. For a given $U'/U$, when $t + \lambda$ increases, quantum fluctuations are enhanced gradually to destroy the FM order so the area of FM phase shrinks. Since the properties of MI phases have been discussed in Section II, we focus on the properties of SF phases below.

To address the different magnetic properties between the FM SF phase and chiral SF phase, we show $S_{ij}$ and $\kappa_{ij}$ in Fig. 6. As we show in panel (a), $S_{ij}$ is finite in large $|i - j|$ limit at $(\eta, t + \lambda) = (0.0833, 0.48U)$ belonging to the FM SF phase, indicating the emergence of long-range FM order. On the other hand, at $(\eta, t + \lambda) = (0.5, 0.48U)$ for the chiral SF phase, $S_{ij}$ decays in a power-law form as a function of $|i - j|$, which can be well fitted by the same function as that in the chiral MI phase. Moreover, the relation $q_x = \pi/2$ for the peak position at $\eta = 0.5$ remains satisfied in the chiral SF phase, which is strictly protected by the symmetric transformation. In panel (b), we show $\kappa_{ij}$ as a function of $|i - j|$. As expected, $\kappa_{ij}$ is exponentially small in the FM SF phase but nearly a finite constant in the chiral SF phase, revealing a long-range chiral order. Since strikingly different from the MI phases, the SF phases at least involve one of the kinetic energy term and the SOC term being comparable or even dominant over the interactions. It is interesting to understand how the motion process of bosons ensures the magnetic structures. For this purpose, we sketch a simple picture shown in Fig. 7. When $t \gg \lambda$, the SOC might be neglected. A polarized configuration, as we show in panel (a), is energetically favored because $U'$ is larger than $U$. In this case, it is effectively a one-component system. The particle can only hop within the same component. When $\eta$ increases, the probability of hopping between different components increases as well, eventually destroying the FM order. The strong competition between the kinetic energy and the SOC results in a chiral SF phase. As $\eta$ approaches 1, i.e., $\lambda \gg t$, only particle tunneling between different components is allowed, and thus configuration in panel (c) is energetically favored, giving rise to a AF SF phase.

Finally, we elucidate the SF nature of the FM and the chiral SF phases by calculating the one-body density matrix which is defined by

$$n_{ij}^\sigma = \langle \psi_0 | \hat{c}^\dagger_{i\sigma} \hat{c}_{j\sigma} | \psi_0 \rangle,$$
and the momentum distribution is given as

$$n^\sigma(q) = \frac{1}{L} \sum_{i,j} e^{iq(i-j)\eta_{ij}}, \quad (18)$$

where $|\psi_0\rangle$ is the ground state of Hamiltonian $H$. In one dimension, there is no true condensation due to strong quantum fluctuation. Instead, the SF is characterized by the power-law behavior of the one-body density matrix $n^\sigma_{ij}$,

$$n^\sigma_{ij} \sim \cos(|i-j|q_n + \delta_n)/|i-j|^{\alpha_n}. \quad (19)$$

where $q_n$ corresponds to the peak position of $n^\sigma(q)$. This formula is applicable for all SF phases. In particular, in conventional SF phases, $q_n = 0$, or $\pi/2$, corresponding to the FM SF or SF AF. While in the chiral SF phase, $q_n \in (0, \pi/2)$. This incommensurability for $n^\sigma(q)$ results from the competition between the kinetic energy and the SOC. In the left panel of Fig. 9, we show $n^\sigma_{ij}$ as a function of $|i-j|$ at $(\eta, t + \lambda) = (0.5, 0.48U)$, which belongs to the chiral SF phase. In this case, fitting the numerical data with $q^\sigma\gamma_n$ gives rise to $n^\gamma_{ij} = \cos(|i-j|\pi/4 - 0.116)/|i-j|^{0.3}$. We noticed that $q^\gamma_n = \pi/4$, which is half of $q_n$ obtained by fitting $S^\gamma_{ij}$ of Fig. 7 with Eq. 13 at the same parameters. Indeed, Eq. 19 is directly related to Eq. 13 and $q_n/q_s = 1/2$ always holds, not just at $\eta = 0.5$. This relation is verified for more $\eta$ by the DMRG calculations in the right panel of Fig. 9, where $q_n$, $q_s$, and $2q_n$ are plotted as a function of $\eta$ for $t + \lambda = 0.48U$, $U' = 1.2U$. Open circle is for $q_n$, open square is for $q_s$, and red cross is for $2q_n$.
on $\eta$. These results may reflect a close relation between magnetic structures and SF pattern. Finally, we remark that the incommensurability of the momentum distribution with $q_n \in (0, \pi/2)$ signals the difference between the chiral SF phase and the FM (AF) SF phase. The former has never been reported in TBHM, but shows up in a wide region in the presence of the SOC, demonstrating a peculiar feature arising from the competition between the kinetic energy and the SOC.

IV. CONCLUSIONS

In conclusion, we studied the evolution of the magnetic structure under a synthetic spin-orbit coupling in one-dimensional two-component Bose-Hubbard model with $U' > U$ by using density-matrix renormalization group method. When $t + \lambda$ is small and at the unit filling, three magnetic MI phases are found: a gapped FM phase, a gapless chiral phase and a gapped AF phase. These magnetic orders persist to SF phases, leading to three different SF phases. In particular, in the chiral MI phase and chiral SF phase, the asymptotic behaviors of characteristic correlation functions are modulated incommensurately, demonstrating the novel effects on the competition between the kinetic energy and the spin-orbit coupling. We believe that our findings will inspire further theoretical and experimental investigations on the effects of the spin-orbit coupling in lattice bosonic systems.

V. ACKNOWLEDGEMENTS

The computational resources are provided with the high-performance computer-Kohn at physics department, RUC. P. Zhang is supported by NSFC 91321103, X. Q. Wang is supported by MOST 2012CB921704 and NSFC 11174363.

Note added After we post this paper, three papers on the similar topic appear\cite{17, 18, 19}.
