Carbon capture and utilization has been proposed as one strategy to combat global warming. Microbial electrolysis cells (MECs) combine the biological conversion of carbon dioxide (CO2) with the formation of valuable products such as methane. This study was motivated by the surprising gap in current knowledge about the utilization of real exhaust gas as a CO2 source for methane production in a fully biocatalyzed MEC. Therefore, two steel mill off-gases differing in composition were tested in a two-chamber MEC, consisting of an organic substrate-oxidizing bioanode and a methane-producing biocathode, by applying a constant anode potential. The methane production rate in the MEC decreased immediately when steel mill off-gas was tested, which likely inhibited anaerobic methanogens in the presence of oxygen. However, methanogenesis was still ongoing even though at lower methane production rates than with pure CO2. Subsequently, pure CO2 was studied for methanation, and the cathodic biofilm successfully recovered from inhibition reaching a methane production rate of 10.8 L m−2 d−1.

Metagenomic analysis revealed Geobacter as the dominant genus forming the anodic organic substrate-oxidizing bioanode, whereas Methanobacterium was most abundant at the cathodic methane-producing biofilms.

Introduction

Global warming caused by anthropogenic greenhouse gas emissions is becoming a serious problem for the environment and all forms of life (Bajracharya et al., 2017). Carbon dioxide (CO2), as one of the main contributors of greenhouse gases, is mainly released by human activities such as burning fossil fuels or deforestation (Pachauri and Meyer, 2014). These activities have increased the atmospheric CO2 concentrations...
annually since the industrial age, and half of the CO₂ emissions between 1750 and 2011 have occurred in the last 40 years (Pachauri and Meyer, 2014). To combat global warming CO₂ mitigation technologies, such as carbon capture and storage (CCS) and carbon capture and utilization (CCU), have been proposed as strategies (Bian et al., 2020). Therefore, biological CO₂ conversion with microbial electrolysis cells (MECs) attracted great interest. Bioelectrochemical systems are based on the electroactivity of microorganisms attached to the electrode(s), which release electrons to the anode during substrate oxidation or receive electrons from the cathode during substrate reduction (Rabaey and Rozendal, 2010). MEC technology combines CO₂ reduction with the production of versatile chemical compounds, such as methane (CH₄), acetate, and ethanol, supported by a low energy input (Zhang and Angelidaki, 2014; Kadier et al., 2016). In particular, the production of CH₄ attracts attention, because it is thermodynamically the most favorable product for CO₂ reduction (Eq. 1) (Jiang et al., 2019).

\[
\text{CO}_2 + 8\text{H}^+ + 8\text{e}^- \rightarrow \text{CH}_4 + 2\text{H}_2\text{O} \quad \text{–0.244 V vs. SHE} \quad (1)
\]

Methanogenic archaea can use CO₂, as a terminal electron acceptor, and hydrogen (H₂), as an electron source, to produce CH₄ as a metabolic product (Bajracharya et al., 2017). These microbes serve as biocatalysts for CO₂ reduction in MECs, a process referred to as electromethanogenesis (Cheng et al., 2009). Electromethanogenesis can proceed via direct extracellular electron transfer or indirectly via (bio)electrochemically produced H₂, formate or acetate (Van Eerten-Jansen et al., 2015). An oxidation reaction at the anode supplies electrons and protons for a reduction reaction. For instance, water oxidation can occur at the anode of a MEC. However, also an organic substrate-oxidizing bioanode can be coupled to a CH₄-producing biocathode to reduce the external power supply (Villano et al., 2010) as shown in Figure 1. Recently, an increasing number of research groups have been focusing on this energy-efficient fully biocatalyzed MEC, investigating the effects of the anodic potential settings (Villano et al., 2016), testing the sequential polarization of the anodic and cathodic chambers (Zeppilli et al., 2019), as well as electrode modifications and their effect on performance parameters (Seelajaroen et al., 2020). Lately, microbial electrosynthesis from unpurified CO₂ from brewery industry was tested for the first time within a bioelectrochemical reactor, consisting of a biotic cathode and an abiotic anode, producing acetate at a rate of 0.26 g L⁻¹ d⁻¹ (Roy et al., 2021). Also, real exhaust gas from a coal-fired power plant was used as a feedstock for lycopene production in a single bioelectrochemical reactor (Wu et al., 2022). On the other hand, to the best of our knowledge, exhaust gas has not been studied in a fully biocatalyzed CH₄ producing MEC so far. Therefore, the present study aimed to explore the CH₄ production by utilization of CO₂ rich exhaust gas in a MEC, consisting of a bioanode and a biocathode, and to investigate how exhaust gas composition may influences the microbial activity. Two H-type MECs, referred to as MEC1 and MEC2, were setup. MEC1 was flushed with pure CO₂, whereas in MEC2 the usage of exhaust gas was examined.
Furthermore, prokaryotes on bioelectrodes of MEC2 were identified after exhaust gas flushing and were compared to MEC1, which was flushed with pure CO₂, to discuss microbial community changes due to exhaust gas flushing. As steel production is one of the most energy-intensive processes, emitting 7% of the global CO₂ emissions (Holappa, 2020), steel mill off-gas was selected as the exhaust gas. Two steel mill off-gases differing in composition were tested in MEC2 by applying a constant potential on the bioanode. Setting the anode potential at a fixed value offers some advantages as described recently (Villano et al., 2016). First, it leads to a faster start-up regarding organic substrate degradation as well as current generation. Second, fixing the anode potential regulates the biological activity and underlying electron transfer mechanisms of microorganisms (located on both electrodes). Furthermore, the cathode potential will get adjusted to sustain the current generating anode. Throughout all experiments process parameters, such as chemical oxygen demand (COD) removal and CH₄ production, were monitored. Further, Coulombic efficiencies and energetic parameters were calculated. Also, the CH₄ production rate was compared with other studies, which investigated two-chamber CH₄ producing MECs.

Materials and methods

MEC setup

The experiments were performed in two-chamber H-cells with a working volume of 220 ml each, separated by a pretreated proton exchange membrane (Naion 117, Chemours, Wilmington, DE, United States), as previously described (Spiess et al., 2021). Two MECs were set up and referred to as MEC1 and MEC2. Carbon felt (projected surface area 15 cm², Alfa Aesar, Heysham, United Kingdom) was selected as an electrode material. Prior to use, the carbon felt electrodes were pretreated with isopropanol and hydrogen peroxide as described elsewhere (Spiess et al., 2021). Titanium wires (0.25 mm, Alfa Aesar, Heysham, United Kingdom) were used to enable the external electrical connection. Ag/AgCl reference electrodes were placed in both MEC chambers. All voltages reported in this study are with respect to Ag/AgCl reference electrode (3 M NaCl, +209 mV vs. standard hydrogen electrode). 200 ml phosphate buffer solution (PBS, pH 7.2) was used as an electrolyte for both chambers, consisting of the following components (per liter): 3 g KH₂PO₄, 2.5 g K₂HPO₄, 0.13 g NaCl, 0.31 g NH₄Cl, 6 g NaHCO₃, 0.04 g MgSO₄·7H₂O, 12.5 ml tris buffer solution SL 10 (DSMZ 320), and 5 ml vitamin solution (DSMZ 141). All MEC chambers were inoculated with 20 ml anaerobic digester sludge collected from a wastewater treatment plant. Prior to inoculation, solid contaminants were removed by centrifugation at 2,150 g for 10 min. All experiments were performed at room temperature, and the anolytes and catholytes were continuously mixed at 70 rpm using a magnetic stirrer IKA RCT basic (Staufen, Germany).

MEC operation

During the experiments, the anode chambers of MEC1 and MEC2 were supplied with acetate (1 g L⁻¹) three times per week, whereas the cathode chambers were flushed with pure CO₂ (99.995 vol%) or steel mill off gas (SMO). 100% of the anolyte and 90% of the catholyte were replaced with fresh PBS at each feeding. Before each feeding, liquid and gas samples were taken from anode and cathode chambers, respectively. MEC bioanodes were maintained under anaerobic conditions during all experiments by flushing with pure CO₂ after each feeding. Experimental procedures are summarized in Table 1. During adaptation MECs were operated in duplicate by applying a constant potential of +400 mV vs. Ag/AgCl on the anode using a PM-100 potentiostat (Jaissle Elektronik GmbH, Münster, Germany), and the CH₄ production using pure CO₂ for flushing the biocathode was evaluated. In experiment 1 an exhaust gas was tested in MEC2 by purging the cathode at each feeding with SMO, whereas MEC1 was flushed with pure CO₂ as a control. A total of six feeding cycles were repeated. The composition of the first steel mill off-gas (SMO-1) used was as follows: 73.4 vol% N₂, 22 vol% CO₂, and 4.6 vol% O₂. Afterwards, the catholyte from MEC2 was flushed again with pure CO₂ instead of exhaust gas for six feeding cycles. During adaptation and experiment 1 an anodic potential of +400 mV vs. Ag/AgCl was set, as a high potential probably leads to a faster start-up time and to a thicker biofilm formation as described elsewhere (Wagner et al., 2010). Finally, the biofilms were scraped from all MEC1 and MEC2 bioelectrodes, resuspended in Tris-EDTA buffer (pH 8.0), and frozen at −80°C. In experiment 2 the applied anode potential was reduced from +400 mV to +300 mV vs. Ag/AgCl in MEC1 and MEC2, and was tested for eight feeding cycles to investigate the effects of a reduced potential on CH₄ production rates. The CH₄ production by utilization of the second steel mill off-gas (SMO-2) was investigated in experiment 3 in MEC2 by applying a constant anodic potential of +300 mV vs. Ag/AgCl for six feeding cycles. The composition of SMO-2 used was as follows: 74.2 vol% N₂, 23.1 vol% CO₂, and 2.7 vol% O₂. MEC1 served as a control during this experiment and was purged with pure CO₂. During the experiments the cathode potentials of MECs were monitored once per day with a Voltcraft VC880 multimeter (Hirschau, Germany).

Analytics and calculations

A COD test was used to estimate the content of organic compounds as previously described (Spiess et al., 2021). The COD removal efficiency was calculated according to Eq. 2 in which ΔCOD represents the depleted COD, and COD₀ is the COD of a provided substrate.
TABLE 1 Overview of the experimental conditions of MEC1 and MEC2.

| Experimental conditions | Reactors          | Applied potential vs. Ag/AgCl | Cycles | Anode chamber feeding | Cathode chamber flushing |
|-------------------------|-------------------|-------------------------------|--------|-----------------------|------------------------|
| Adaptation              | MEC1 and MEC2     | +400 mV                       | Approx. 3 months | 1 g L⁻¹ acetate       | CO₂                    |
| 1                       | MEC1 (control)    | +400 mV                       | 12      | 1 g L⁻¹ acetate       | CO₂                    |
|                         | MEC2              | +400 mV                       | 6       | 1 g L⁻¹ acetate       | SMO-1                  |
|                         | MEC2              | +400 mV                       | 6       | 1 g L⁻¹ acetate       | CO₂                    |
| 2                       | MEC1 and MEC2     | +300 mV                       | 8       | 1 g L⁻¹ acetate       | CO₂                    |
| 3                       | MEC1 (control)    | +300 mV                       | 6       | 1 g L⁻¹ acetate       | CO₂                    |
|                         | MEC2              | +300 mV                       | 6       | 1 g L⁻¹ acetate       | SMO-2                  |

\[
COD\text{ removal efficiency} \ (\%) = \frac{\Delta COD}{COD_{IN}} \times 100 \tag{2}
\]

The CH₄ production in MECs was analyzed by injecting a 2 ml sample from the cathode’s headspace into a 6890 GC system (Agilent Technologies, Santa Clara, CA, United States), equipped with a flame ionization detector and a series-connected helium ionization detector. The Coulombic efficiency (CE) was calculated according to Eq. 3, in which \(V_{CH4}\) represents the CH₄ production in m³, eight electrons are required to reduce CO₂ to CH₄, \(F\) is the Faraday constant (96,485 C mol⁻¹), \(V_m\) is the molar volume (0.0252 m³ mol⁻¹), \(I\) represent the recorded current, and \(t\) means the time.

\[
CE\text{ cathode} (\%) = \frac{V_{CH4} \times 8 \times F}{V_m \times \int_0^t Idt} \times 100 \tag{3}
\]

The energy consumptions for COD removal (kWh kg⁻¹ COD) and CO₂ removal (kWh Nm⁻³ CO₂) were calculated for standard conditions as described elsewhere (Geppert et al., 2016; Zeppilli et al., 2019). The energy efficiency (\(\eta_E\)) was calculated according to Eq. 4, in which \(\Delta G_{CH4}\) represents the Gibbs free energy of CH₄ oxidation (890.4 kJ mol⁻¹), while \(V_{CH4}\) is the CH₄ production in m³, \(V_m\) (0.0252 m³ mol⁻¹) is the molar volume, \(E_{Cell}\) is the cell voltage, \(I\) represent the recorded current, and \(t\) means the time.

\[
\eta_E = \frac{-\Delta G_{CH4} \times V_{CH4}}{V_m \times E_{Cell} \times \int_0^t Idt} \tag{4}
\]

Metagenomic analysis

Microbial DNA was isolated using the DNeasy UltraClean Microbial Kit (Qiagen, Germany), according to the manufacturer’s instructions. The hypervariable V4 region of 16S rRNA was selected to analyze prokaryotes, and the gene encoding the \(\alpha\)-subunit of methyl coenzyme M reductase (\(mcrA\)) was used for the analysis of methanogenic archaea. The hypervariable region V4 was amplified with unique barcoded oligonucleotides 515F and 806R, as previously described (Spiess et al., 2021). The \(mcrA\) gene was amplified with gene-specific oligonucleotides qmcrA-F and mcrA-rev (Denman et al., 2007; Steinberg and Regan, 2008) containing Illumina adapter overhang nucleotide sequences (Supplementary Table S1). PCR amplification was performed using Platinum II Taq Hot-Start DNA polymerase (Thermo Fisher Scientific, United States), as follows: initial DNA denaturation step at 95°C for 3 min, 25 cycles of DNA denaturation at 94°C for 20 s, annealing at 60°C for 30 s with a 50% thermal ramp, extension at 72°C for 30 s, and a final extension step at 72°C for 5 min. The amplification products were purified using the UltraClean PCR Clean-Up Kit (Qiagen, Germany), according to the manufacturer’s instructions. Each purified PCR sample was tagged with sequencing adapters using the Nextera XT Indexes Kit (Illumina, United States) and KAPA HiFi HotStart ReadyMix PCR Kit (Kapa Biosystems, United States), according to the manufacturer’s specifications. The indexed products were purified by Agencourt® AMPure XP beads (Beckman Coulter, United States) according to Illumina recommendations with a final elution step of 25 μl to maintain a high concentration of amplicons. Samples were quantified using a Qubit 4.0 fluorometer (Thermo Fisher Scientific, United States), followed by manual normalization to the lowest observed concentration and pooling to create the final library. The Fragment Analyzer (Advanced Analytical Technologies, United States) was then used to determine the quality of the library. The library was sequenced using a MiSeq System (Illumina, United States) with MiSeq Mid Output Kit (300 cycles). Raw fastq reads were processed in R software (4.0.3) using the open-source package DADA2 (1.16.0), as previously described (Spiess et al., 2021). 16S rRNA gene sequences were analyzed using the Silva database (Quast et al., 2013), while a \(mcrA\) ARB database was used to analyze \(mcrA\) sequences (Angel et al., 2012). The summaries
of all 16S and mcrA amplicon sequence variants (ASVs) are shown in Supplementary Tables S2, S3, respectively. Datasets generated and analyzed during this study are available in the NCBI Sequence Read Archive under project number BioProject ID: PRJNA782972.

Results and discussion
Methane production by utilization of SMO-1

First, the CH₄ production using pure CO₂ was investigated in MEC2, then the CH₄ production with exhaust gas was evaluated. Thus, the cathode chamber of MEC2 was flushed with SMO-1 at each feeding, MEC1 served as a control during this experiment. Figure 2 illustrates the CH₄ production per projected electrode surface area and day and the current density per projected electrode surface area of MEC2. Flushing MEC2 with pure CO₂ resulted in a maximum CH₄ production rate of 14.1 L m⁻² d⁻¹. However, after the first flushing of the MEC2 biocathode with SMO-1 the CH₄ production dropped immediately to 3.6 L m⁻² d⁻¹. After the second flushing the CH₄ production was further halved to 1.8 L m⁻² d⁻¹. The CH₄ production significantly decreased after flushing with SMO-1 (p < 0.001; t-test) and subsequently stabilized at an average of 0.9 L m⁻² d⁻¹. The current density during this experiment was in a range of 6.7–8.0 A m⁻². The cathode potential of MEC2 was on average -1,180 ± 54 mV during SMO-1 and -1,151 ± 66 mV during CO₂ flushing. The significant reduction in CH₄ production was most likely due to the elevated O₂ concentration (4.6 vol%) in SMO-1, which most likely caused strong inhibition of anaerobic methanogens. In addition, GC analysis of the cathodic headspace samples revealed a threefold increase in the H₂ concentration, but no further conversion to CH₄. However, it is noticeable that methanogenesis was still ongoing in the presence of O₂ from SMO-1 even though at lower CH₄ production rates than before.

After six cycles using SMO-1 the MEC2 biocathode was flushed again with pure CO₂. A significant increase in CH₄ production was observed again during CO₂ re-flushing (p < 0.001; t-test). The CH₄ production increased immediately to 5.4 L m⁻² d⁻¹ and continued to rise steadily up to 10.8 L m⁻² d⁻¹ at day 32 (Figure 2). In addition, CH₄ production differed significantly during the first and second purging with pure CO₂ (p < 0.01; t-test). However, the elevated recovery of CH₄ production rate of the biocathode after the re-flushing with pure CO₂ suggested a return to the initial values after day 32. Thus, the CH₄-producing biofilm adhering to the MEC2 biocathode successfully recovered from O₂ inhibition caused by flushing with SMO-1. Although methanogens are strict anaerobic, mixed methanogenic cultures may be able to tolerate a certain amount of O₂ for a short time (Zitomer and Shrou, 2000). As MEC2 was inoculated with a mixed culture from sewage sludge and has been adapted for approximately 3 months before exhaust gas was flushed, a very robust biofilm may have developed on the cathode. Nevertheless, the biofilm got inhibited during SMO-1 flushing. However, probably due to the long adaptation and the mixed inoculum this concentration of O₂ did not harm methanogens irreversible.

Table 2 compares the CH₄ production of MEC2 from this study (when flushed with pure CO₂ at +400 mV vs. Ag/AgCl) with other studies. The CH₄ production rates were found to range widely from 0.017 to 0.678 mmol L⁻¹ h⁻¹. On the other hand, the cathodic CE showed higher similarity among all studies, ranging from 55 to 74%. The MEC operating conditions differ in potentiostatic control of the anode or cathode. If the cathodic potential was controlled, the CH₄ production rates ranged from 0.035 to 0.678 mmol L⁻¹ h⁻¹, whereas controlling the anode showed lower production rates varying from 0.017 to 0.339 mmol L⁻¹ h⁻¹. Thus, the result of this study (0.150 mmol L⁻¹ h⁻¹) was within the range of other studies. If an organic substrate oxidizing-bioanode is coupled to a CH₄-producing biocathode, electromethanogenesis seems to strongly depend on the amount of organic substrate provided, accompanied by COD removal efficiency and the produced current density. In our previous study, the COD of the supplied substrate was 600 mg L⁻¹ (fed twice weekly), resulting in a CH₄ production of 0.018 mmol L⁻¹ h⁻¹ (Spiess et al., 2021). Whereas, in this study, the bioanode was provided with 1,000 mg COD L⁻¹ (three times weekly), resulting in an eightfold higher CH₄ production rate (0.150 mmol L⁻¹ h⁻¹).

Effect of the applied anode potential

In experiment 2 the effect of the applied anode potential on the CH₄ production when pure CO₂ was flushed was investigated. Therefore, the anode potential of MEC1 was reduced from +400 mV to +300 mV vs. Ag/AgCl. Figure 3 illustrates the CH₄ production and the cathode potential of MEC1 at +400 mV and +300 mV vs. Ag/AgCl, respectively. The CH₄ production at +400 mV ranged between 7.5 L m⁻² d⁻¹ and 10.8 L m⁻² d⁻¹, and at +300 mV between 6.7 L m⁻² d⁻¹ and 9.9 L m⁻² d⁻¹, respectively. The difference in CH₄ production by applying an anode potential of either +400 or +300 mV was insignificant (p > 0.05; t-test). The cathode potentials of MEC1 fluctuated at an applied potential of +400 mV from -883 mV to -1,198 mV, and at +300 mV from -1,066 mV to -1,192 mV vs. Ag/AgCl. The average cathodic potential was -1,101 ± 90 mV and -1,134 ± 45 mV at +400 mV and +300 mV vs. Ag/AgCl, respectively. Also, previous mentioned results from MEC2 (1,151 ± 66 mV...
during CO₂ flushing) are in a similar range and suggest a stable cathode potential during the experiments.

The performance parameters of MEC1 at applied anode potentials of +400 and +300 mV vs. Ag/AgCl are summarized in Table 3. The average CH₄ production remained nearly constant at 8.8 L m⁻² d⁻¹ despite the reduced potential. In contrast at an applied potential of +300 mV, a higher current density, and COD removal efficiency of 6.4 A m⁻² and 53%, respectively, were observed. The cathodic CE dropped from 65% at +400 mV to 61% at +300 mV. As the CH₄ production

remained constant despite the reduced applied potential and the current density and COD removal efficiency increased, an applied anode potential of +300 mV vs. Ag/AgCl was used for all further experiments for both MECs. Furthermore, the CH₄ production in the bioanode of MEC1 was nominal (<1% CH₄ was detected in the anodic headspace). This may be related to the slightly acidic pH (approx. 6.2) of the anolyte, which was measured after each feeding cycle, because methanogens are known to be inhibited easily at pH values < 6.3 and > 7.8 (Chae et al., 2010).

Methane production by utilization of SMO-2

Furthermore, the methanation of SMO-2 was tested in MEC2 by applying an anode potential of +300 mV vs. Ag/AgCl. However, the O₂ concentration in SMO-2 was only 2.7 vol% compared to 4.6 vol% in SMO-1. Figure 4 shows the cumulative CH₄ production of the MEC2 biocathode when flushed with pure CO₂, or SMO-1 and SMO-2 containing 4.6 vol% and 2.7 vol% O₂, respectively. The cumulative CH₄ production during pure CO₂ flushing was significantly higher than during SMO-1 and SMO-2 flushing ($p < 0.001$; ANCOVA). In addition, a significant difference in CH₄ production was observed between SMO-1 and SMO-2 ($p < 0.001$; ANCOVA). The highest cumulative CH₄ production (843 ml L⁻¹) was achieved when the biocathode was flushed with pure CO₂ and the lowest (133 ml L⁻¹) when purged with SMO-1 containing 4.6 vol% O₂ (here an anode potential of +400 mV vs. Ag/AgCl was applied). During the experiment with SMO-2, containing 2.7 vol% O₂, the cumulative CH₄ production was nearly three times higher (382 ml L⁻¹) than with SMO-1. The obtained results demonstrated that the O₂ concentration in the exhaust gas strongly affected CH₄ production in MEC2 due to the inhibition of anaerobic methanogens. As well-known methanogens are strictly anaerobic and very sensitive to even low levels of O₂ (Garcia et al., 2000), hence higher CH₄ production rates can be expected at lower O₂ concentrations in exhaust gas streams. Moreover, it is also possible that during SMO flushing other products/intermediates such as acetate have been formed in the cathode chamber. There are several suggested pathways for bioelectrochemical CH₄ production. Apart from CH₄ production, via direct or indirect electron transfer, formation of other products could have occurred at the MEC cathode. For instance, H₂ can be produced either electrochemically or bioelectrochemically and can be further used for the formation of CH₄, acetate or formate. Moreover, CH₄ can be also produced in a second step via bioelectrochemically produced acetate (Van Eerten-Jansen et al., 2015). However, during pure CO₂ flushing no acetate formation was detected in the catholytes of MECs.

Energetic evaluation

Table 4 summarizes the calculated energetic parameters for each experimental condition. The energy efficiency ($\eta_E$) was 48% and 49% for MEC1 at +400 mV and +300 mV vs. Ag/AgCl, respectively, and in both cases pure CO₂ was used for methanation. These results are comparable with a previous study of a CH₄ producing MEC for biogas upgrading at anodic potentiostatic control, where an energy efficiency of 52% was reported (Zepplini et al., 2019). However, when exhaust gas was used for flushing MEC2 cathode, the energy efficiency dropped to 6% with SMO-1 and to 19% with SMO-2. This decrease may be related to the lower CH₄ production rates of
the biocathode due to the presence of inhibiting O₂ concentrations in the exhaust gases. Furthermore, the energy consumptions for COD and CO₂ removal were calculated. The energy consumptions for CO₂ removal in MEC1 at +300 mV (20 kWh Nm⁻³) and +400 mV (20 kWh Nm⁻³) vs. Ag/AgCl were considerably higher compared to a previous reported one (4.27 kWh Nm⁻³) of a MEC for ammonium recovery and biogas upgrading at an applied anode potential of +200 mV vs. SHE (Zeppilli et al., 2021). In a next step the bioelectrochemically transformed CO₂ from SMO could be used directly as a CH₄ source in different industries, as for example the steel sector. For instance, this CH₄ may be used as an alternative reducing agent in the blast furnace for the partial substitution of coke. This will cause a reduction of the CO₂ emissions, due to the lower footprint of biological produced CH₄ in comparison with coke (Remus et al., 2013). Furthermore, these observations may be interesting for other industry sectors, where exhaust gases with lower O₂ concentrations are produced, which may allow its direct usage in the MEC without any previous separation step.

### Analysis of microbial community on electrode biofilms

The 16S sequencing of the biofilms in MECs revealed a high proportion of bacteria adhering to anodes (95–100%) (Figure 5A), whereas archaea adhered predominantly to cathodes (89–91%) (Figure 6A). The distribution of bacteria was further divided into different taxonomic ranks based on the 16S sequencing (Figures 5B, 6C). Considering the significant proportion of archaea in CH₄-producing cathodic biofilms, additional mcrA sequencing was performed to determine more accurately the distribution of methanogenic archaea into different taxonomic ranks (Figure 6B). For a comprehensive analysis, non-CH₄-producing anodic biofilms were also analyzed using mcrA sequencing (Figure 5C).

Geobacter was the predominant genus adhered to MEC1 (64.6%) and MEC2 (72.5%) bioanodes, one of the prominent representatives using electrodes as electron acceptors for anaerobic respiration (Bond and Lovley, 2003). This genus can produce electrons and transfer them through conductive pili to the anode, whereas many other exoelectrogens need
direct contact with the electrode (Logan et al., 2019). In particular, Geobacter sulfurreducens is known to produce very high current densities (Yi et al., 2009). The second most abundant genus attached to both bioanodes was Phascolarctobacterium with 9.3% (MEC1) and 5.3% (MEC2). This genus has also been identified in microbial fuel cells of other studies (Borole et al., 2009; Liu et al., 2013). Interestingly, Oscillibacter (4.2%), Castellaniella (4.3%), and Acidaminococcaceae (3.6%) were only identified at MEC1 bioanode, resulting in a higher biodiversity compared to MEC2. Castellaniella has been previously detected in the anodic biofilm and may contribute to electricity generation (Sun et al., 2011). In addition, differences in archaea abundance were observed between MEC1 and MEC2 bioanodes with 0.3% (MEC1) and 5.2% (MEC2).

The anodic biofilm in MEC1 was predominated in terms of archaea by Methanobacterium (67.2%), whereas Methanocorpusculum (88.2%) was predominant in anodic MEC2 biofilm. Methanoseta (9.2%), present only in MEC1, can convert acetate, the primary carbon source in the anodes of both MECs, to CH₄ but cannot use H₂ or formate as an electron source for methanation (Smith and Ingram-Smith, 2007). Moreover, Methanoseta spp. and Geo bacter spp. can synergize through electron exchange, referred to as direct interspecies electron transfer (Rotaru et al., 2014; Zhao et al., 2015; Lovley, 2017). Differences in the anodic archaea population of MEC1 and MEC2 may be attributed to O₂ diffusion across the membrane, since the cathode of MEC2 was flushed with SMO-1 containing 4.6 vol% O₂. O₂ diffusion mechanisms from the anode to the biocathode were previously mentioned as a causer for parasitic reactions such as direct O₂ reduction, leading to an increased current production but lower Coulombic efficiencies (Van Eerten-Jansen et al., 2012; Batlle-Vilanova...
et al., 2017). Therefore, O₂, introduced by flushing the cathode chamber of MEC2 with SMO-1, may have diffused the opposite direction from the cathode to the anode, and has probably caused a shift in the archaea population of MEC2 if compared to MEC1.

*Methanobacterium* was found to be the dominant archaeon in CH₄-producing cathodic biofilms (52.5% in MEC1 and 55.8% in MEC2). *Methanobacterium* is a typical member of biofilms attached to cathodes which can perform methanogenesis by direct electron uptake (Siegert et al., 2015). One of the prominent species performing electromethanogenesis is *Methanobacterium palustre* (Cheng et al., 2009). Genus *Methanobrevibacter* (3.4%) was only identified in the MEC2 biofilm. In a previous study this obligate anaerobic archaea mainly dominated cathodes with catalysts, such as platinum, supporting abiotic H₂ production (Siegert et al., 2015). *Methanobrevibacter* is a strictly hydrogenotrophic archaeon that uses only H₂ and CO₂ to produce CH₄, whereas *Methanobacterium* can also ferment acetate, ethanol and methanol (Cai et al., 2022). The use of SMO-1, to flush the biocathode of MEC2, probably affected the biofilm composition leading to a higher archaea diversity in MEC2. Furthermore, a high proportion of other uncharacterized species (41–48%) was observed in both biocathodes. Also, the presence of *Methanobrevibacter* in MEC2 may have been influenced by flushing with SMO-1 as the H₂ concentration in the cathodic headspace have increased by three times during this experiment, which may have enhanced the growth of hydrogenotrophic *Methanobrevibacter*.

The most abundant bacteria were *Desulfovibrio* (39.3%) at MEC1 and *Acetoanaerobium* (41.8%) at MEC2 biocathodes. The anaerobic genus *Acetoanaerobium* produces acetate by metabolizing...
H₂ and CO₂ (Sleat et al., 1985), whereas Desulfovibrio spp. are well known for producing H₂ when attached to an electrode surface (Jafary et al., 2015). In a previous study (Zheng et al., 2021) interspecies electron transfer between Methanobacterium and Desulfovibrio was studied, suggesting that Methanobacterium spp. can actively accept electrons from electron donating Desulfovibrio spp. If strictly anaerobic Methanobacterium got inhibited due to cathodic SMO-1 flushing of MEC2, this may have influenced the syntrophic co-culture of Methanobacterium and Desulfovibrio, and possibly led to a shift in the bacterial community composition and suppressed genus Desulfovibrio, as observed when bacterial communities of MEC1 and MEC2 cathodes are compared, in which Desulfovibrio and Acetanaerobium have predominated, respectively. In addition, the genera Syner-01, Synergistaceae, and Wolinella were present in MEC1 and MEC2 bioelectrodes, whereas the genus Lentimicrobium (6.1%) was found only in MEC1.

**Conclusion**

This study investigated for the first time the CH₄ production of a fully biocatalyzed MEC using SMO for flushing the biocathode. Two MECs, consisting of organic substrate-oxidizing bioanodes and CH₄-producing bioelectrodes, were operated by applying a constant anode potential of +300 mV or +400 mV vs. Ag/AgCl. MEC1 served as a control during the experiments, whereas MEC2 was used for tests with SMO. Two exhaust gases with different compositions were examined. Higher O₂ concentrations likely have reduced the rate of CH₄ production during MEC2 operation due to the inhibition of anaerobic methanogens which have colonized the bioelectrode surface. However, it was noticeable that methanogenesis was still occurring in the presence of O₂ from SMO-1 even though at lower CH₄ production rates than before. Upon subsequent methanation by application of pure CO₂, the biofilm successfully recovered from inhibition and achieved a CH₄ production rate of 10.8 L m⁻² d⁻¹. Therefore, separating O₂ from steel mill off-gas seems to be essential to increase CO₂ recycling and CH₄ production rates, as well as to decrease the energy consumption for CO₂ removal in CH₄ producing MECs. Furthermore, the effect on the CH₄ production rate, by reducing the anode potential from +400 to +300 mV vs. Ag/AgCl, was investigated in MEC1. The CH₄ production of MEC1 remained constant despite the reduced anode potential but COD removal efficiency and current density increased. The microbial diversity of bacteria and archaea, attached to both MEC bioelectrodes, was also investigated and compared with each other. The genus Geobacter predominated the anodic biofilms, whereas the genus Methanobacterium was the most abundant one in cathodic biofilms. Differences in microbial community compositions of MEC1 and MEC2 bioelectrodes, which may be related to SMO flushing, have been identified and discussed.

**Data availability statement**

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article/Supplementary Material.

**Author contributions**
