A new family of exactly solvable one dimensional models with a hard-core repulsive potential is solved by the Bethe Ansatz for an arbitrary hard-core radius. The exact ground state phase diagrams in a plane 'electron density - on-site interaction' have been studied for several values of a hard-core radius. It is shown that superconducting phase and strongly interacting Luttinger liquid state coexist simultaneously at positive and finite on-site Coulomb interaction? It turns out that an odd integer liquid state coexist simultaneously at positive and small doping. This coexistence takes place in the framework of the generalized t-J model and the Lai-Sutherland model. The model Hamiltonian includes two terms \( \mathcal{H} = \mathcal{H}_{\text{hop}} + \mathcal{H}_{\text{int}} \)

\[
\mathcal{H}_{\text{hop}} = -t \sum_{<i,j>,\sigma=\uparrow,\downarrow} (\mathcal{P}_c c_{i\sigma}^\dagger c_{j\sigma} \mathcal{P}_c - c_{i\sigma}^\dagger c_{j\sigma} n_{i-\sigma} n_{j-\sigma} \mathcal{P}_c) \]

\[
\mathcal{H}_{\text{int}} = J \sum_{j=1}^L \sum_{\sigma,\sigma'=\uparrow,\downarrow} \left( c_{j\sigma}^\dagger c_{j+1\sigma'}^\dagger c_{j+1\sigma'} c_{j\sigma} + n_{j\sigma} n_{j+1\sigma'} \right) + U \sum_{j=1}^L \sum_{\sigma=\uparrow,\downarrow} n_{j\sigma} n_{j-\sigma},
\]

where \( c_{j\sigma}^\dagger \) and \( c_{j\sigma} \) are the creation and annihilation operators of fermions with spin \( \sigma \), \( \sigma \in \{\uparrow, \downarrow\} \), \( L \) is the total number of lattice sites, \( <i,j> \) stands for neighboring sites, the projector \( \mathcal{P}_c \) forbids two single electrons at distances less than or equal to \( l \) ( \( l \) is measured in units of the lattice spacing parameter), \( t \) is the hopping integral, \( J \) is the constant of the exchange interaction. It is important the \( \mathcal{P}_c \) operator does not forbid doubly occupied lattice sites, it takes place in the so-called \( U \to \infty \) Hubbard model or the t-J model. The last term in (2) is traditionally the most important term for the Hubbard model, the on-site Coulomb repulsion \( U \) separates the energies of single and paired electrons states. The Hamiltonian \( \mathcal{H} \) conserves not only the total number of electrons \( N \) and also the number of single electrons with spin \( \sigma \) \( N_{1\sigma} = \sum_{j=1}^L n_{j\sigma} \) and the number of localized electron pairs \( N_2 = \sum_{j=1}^L n_{j\uparrow} n_{j\downarrow} \). In the case \( t=0 \) and \( J=0 \) the Hamiltonian (1), (2) is reduced to the Lai-Sutherland model. For \( t>0 \) the \( \mathcal{P}_c \) operator is equivalent to additional two particle interactions between single electrons \( \sum_{r=1}^L \sum_{\sigma=\uparrow,\downarrow} n_{r\sigma} n_{r+1\sigma} \). Here \( n_{1\sigma} = \sum_{\sigma=\uparrow,\downarrow} n_{j\sigma} (1-n_{j-\sigma}) \) with infinite \( U_r \) parameters, according to (2) \( U_{l+1} = -J \). Using this representation

The models of strongly correlated electrons with a bound-charge interaction which conserves a number of double occupied sites, are simple examples of strongly correlated electron systems that exhibit superconductivity. The merit of these models is their complete integrability. The phase diagrams in a plane 'electron density - on-site interaction' have four phases, two of them exhibit off-diagonal long-range order (ODLRO) and thus are superconducting. The superconducting phase is realized if the value of the on-site interaction less than the critical one and for \( U=0 \) the Hamiltonian (1), (2) is reduced to the Lai-Sutherland model. The question arises: could the superconducting phase and strongly interacting Luttinger liquid state coexist simultaneously at positive and finite on-site Coulomb interaction? It turns out that an existence of the Fermi surface is not necessary for the superconducting phase.

We shall consider a new family of integrable models and show that superconducting phase and strongly interacting Luttinger liquid states can coexist at a high electron density or at small doping. This coexistence takes place at a repulsive on-site Coulomb interaction the value of which is large than a band width and depends on the value of the hard-core radius. In the models the hopping of single electrons on occupied states are forbidden, whereas the energy of electron pair is finite. In our models we shall use the same hierarchy for the parameters of the interactions, the constants of interactions between single electrons are infinite and define a hard-core radius, the energy of electron pair is finite. We shall consider a new modification of a generalized one-dimensional Lai-Sutherland model for a study of a competition between strongly interacting Luttinger liquid state and superconducting phase. The model Hamiltonian contains kinetic and interaction terms that combine those of the Hubbard model and the Lai-Sutherland model. The model Hamiltonian includes two terms \( \mathcal{H} = \mathcal{H}_{\text{hop}} + \mathcal{H}_{\text{int}} \)

\[
\mathcal{H}_{\text{hop}} = -t \sum_{<i,j>,\sigma=\uparrow,\downarrow} (\mathcal{P}_c c_{i\sigma}^\dagger c_{j\sigma} \mathcal{P}_c - c_{i\sigma}^\dagger c_{j\sigma} n_{i-\sigma} n_{j-\sigma} \mathcal{P}_c) \]

\[
\mathcal{H}_{\text{int}} = J \sum_{j=1}^L \sum_{\sigma,\sigma'=\uparrow,\downarrow} \left( c_{j\sigma}^\dagger c_{j+1\sigma'}^\dagger c_{j+1\sigma'} c_{j\sigma} + n_{j\sigma} n_{j+1\sigma'} \right) + U \sum_{j=1}^L \sum_{\sigma=\uparrow,\downarrow} n_{j\sigma} n_{j-\sigma},
\]

where \( c_{j\sigma}^\dagger \) and \( c_{j\sigma} \) are the creation and annihilation operators of fermions with spin \( \sigma \), \( \sigma \in \{\uparrow, \downarrow\} \), \( L \) is the total number of lattice sites, \( <i,j> \) stands for neighboring sites, the projector \( \mathcal{P}_c \) forbids two single electrons at distances less than or equal to \( l \) ( \( l \) is measured in units of the lattice spacing parameter), \( t \) is the hopping integral, \( J \) is the constant of the exchange interaction. It is important the \( \mathcal{P}_c \) operator does not forbid doubly occupied lattice sites, it takes place in the so-called \( U \to \infty \) Hubbard model or the t-J model. The last term in (2) is traditionally the most important term for the Hubbard model, the on-site Coulomb repulsion \( U \) separates the energies of single and paired electrons states. The Hamiltonian \( \mathcal{H} \) conserves not only the total number of electrons \( N \) and also the number of single electrons with spin \( \sigma \) \( N_{1\sigma} = \sum_{j=1}^L n_{j\sigma} \) and the number of localized electron pairs \( N_2 = \sum_{j=1}^L n_{j\uparrow} n_{j\downarrow} \). In the case \( t=0 \) and \( J=0 \) the Hamiltonian (1), (2) is reduced to the Lai-Sutherland model. For \( t>0 \) the \( \mathcal{P}_c \) operator is equivalent to additional two particle interactions between single electrons \( \sum_{r=1}^L \sum_{\sigma=\uparrow,\downarrow} n_{r\sigma} n_{r+1\sigma} \). Here \( n_{1\sigma} = \sum_{\sigma=\uparrow,\downarrow} n_{j\sigma} (1-n_{j-\sigma}) \) with infinite \( U_r \) parameters, according to (2) \( U_{l+1} = -J \). Using this representation
we can conclude that the kinetic term of the Hamiltonian (1) is a particle-hole invariant: indeed applying this transformation \( c^\dagger_{j\sigma} \rightarrow c_{j\sigma}, c_{j\sigma} \rightarrow c^\dagger_{j\sigma} \), to the Hamiltonian (1), (2) we obtain \( \mathcal{H}(t, J, U) \Rightarrow \mathcal{H}(t, J, U) + U(L - N) \). Due to a particle-hole symmetry the phase diagram is symmetrical with respect to a half filling.

We examine the exact ground state phase diagram for the antiferromagnetic coupling \( J = t \) (we chose the hopping integral equal to unit then the coupling constants are dimensionless) and different values of the hard-core radius. The results of calculations are compared with the ones for \( J = 0 \) - the simplest version of the model.

Direct calculations show that the model (1), (2) is an exactly solvable one by the Bethe ansatz method and the set of the quasimomenta \( \{ k_j \} (j = 1, 2, ..., N_1) \) satisfies the Bethe equations:

\[
\left( \frac{\lambda_j - i/2}{\lambda_j + i/2} \right)^{L - IN_1} = (-1)^{N_1 - 1} \exp(-iP) \prod_{\alpha = 1}^{M} \frac{\lambda_j - \chi_\alpha + i/2}{\lambda_j - \chi_\alpha - i/2},
\]

\[
\prod_{j=1}^{N_1} \frac{\lambda_j - \chi_\alpha + i/2}{\lambda_j - \chi_\alpha - i/2} = -\prod_{\beta=1}^{M} \frac{\lambda_j - \chi_\beta + i}{\lambda_j - \chi_\beta - i},
\]

where \( P = \sum_{j=1}^{N_1} k_j \) is the momentum, \( \lambda_j = \frac{1}{2} \tan \frac{k_j}{\Lambda} \) and \( \chi_\alpha (\alpha = 1, 2, ..., M) \) are the 'charge' and 'spin' rapidities, \( M \) is the number of down spin single electrons.

The eigenvalues and the magnetization are given by

\[
E = -2 \sum_{j=1}^{N_1} \cos k_j + UN_2, \tag{4}
\]

\[
S^z = \frac{1}{2} \sum_\sigma N_{1\sigma} - M. \tag{5}
\]

Let us introduce the partial electron densities: \( n_1 = N_1/L \) is the density of single carriers \( N_1 = \sum_{\sigma = \uparrow, \downarrow} N_{1\sigma} \), \( n_2 = N_2/L \) is the density of localized electron pairs. Clearly \( n = n_1 + 2n_2 \), here \( n = N/L \) is the total density of electrons.

Since the Bethe equations (3) we can calculate exactly the ground state phase diagram as a function of the electron density and an on-site interaction for an arbitrary value of the hard-core radius. The density of localized pairs \( n_2 \) (or \( n_1 \)) can be calculated by minimizing the ground state energy per site \( \mathcal{E} = E/L \) for a fixed total density of electrons

\[
\mathcal{E} = 2n_1 - 2\pi \int_{-Q}^{Q} d\Lambda a(\Lambda) \rho(\Lambda) + Un_2, \tag{6}
\]

where \( a(\Lambda) = \frac{1}{2\pi \Lambda^2 + 1/4} \).

In the thermodynamic limit the Bethe equations reduce to an integral equation of the Fredholm type for the function of the distribution of \( \lambda_j \) on the real axis

\[
\rho(\Lambda) + \int_{-Q}^{Q} d\Lambda' K(\Lambda - \Lambda') \rho(\Lambda') = (1 - \ln(n_1))a(\Lambda), \tag{7}
\]

with the kernel being \( K(\Lambda) = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \exp(-|\omega|) \exp(i\omega \Lambda) \). The \( \Lambda - \) Fermi level denoted as \( Q \) controls the band filling, the density of single electrons is defined by

\[
n_1 = \int_{-Q}^{Q} d\Lambda \rho(\Lambda). \tag{8}
\]

\( Q = 0 \) corresponds to an empty subband of single carriers, \( n_1 = n_0 \) for \( Q \rightarrow \infty \), here \( n_0 = \frac{1}{4(1 + \frac{1}{2})} \) is a 'half-filled' density. Equations (6)-(8) are a consequence of the real solutions for 'charge' and 'spin' rapidities that describe the ground state of the system in the absence of an external magnetic field. We calculate the critical exponent \( \Theta \) for a definition of the realization criterion of strongly interacting Luttinger liquid. We remind the momentum distribution function close to the Fermi momentum \( k_F \) is determined by the critical exponent \( \Theta \)

\[
\langle n_k \rangle \simeq (n_{k_F}) - \text{const}|k - k_F|^{\Theta \text{sgn}(k - k_F)}, \tag{9}
\]

where \( \Theta = (\frac{1}{B} - \frac{1}{\alpha})^2 \) and \( \alpha = 2\sqrt{2}(Q) \) is defined by the dressed charge \( \zeta(\Lambda) \) according to the following integral equation \( \zeta(\Lambda) + \int_{-Q}^{Q} d\Lambda' K(\Lambda - \Lambda')\zeta(\Lambda') = 1 - n_1 \). In the high electron density \( n > 2n_{1\sigma} + n_c \) (where \( n_c \) is solution of equation \( \Theta(n_c) = 1 \)) when the hard-core repulsive potential dominates the behavior of fermions is described as strongly interacting Luttinger liquid with \( \Theta > 1 \).

We have focused on the calculation of the exact ground state phase diagram in the \( n - U \) plane for different values of the hard core radius or \( l \). First we consider peculiarities of behavior of the system using a simple version of the Hamiltonian (1), (2) when \( J = 0 \) and then its transformation for \( J = 1 \). Due to a particle-hole symmetry it is sufficient to discuss the phase diagram for \( n \leq 1 \). For \( J = 0 \) the density of the ground-state energy (6) can be defined analytically \( \mathcal{E} = -2 \frac{1}{\Lambda} \frac{n_1}{\Lambda} \sin \left( \frac{\pi n_1}{4\Lambda} \right) + \frac{\Lambda}{4} U(n - n_1) \), therefore a curve that separates a mixed region is defined according to the following equation

\[
U(n_1) = 4\pi \sin \left( \frac{\pi n_1}{4\Lambda} \right) - \frac{\pi n_1}{4\Lambda} \cos \left( \frac{\pi n_1}{4\Lambda} \right). \tag{10}
\]

\( U \) variances from \(-4 \) at \( n_1 = 0 \) to \( 4(1 + l) \) at \( n_1 \). \( U \) variances from \(-4 \) at \( n_1 = 0 \) to \( 4(1 + l) \) at \( n_1 = n_{\text{max}} = 1/(1 + l) \), hence a maximal value \( U_c = 4(1 + l) \). The value of \( n_c \) is equal to \( n_c = (1 - \sqrt{4 - 4l^2})/l \) for \( l = 1, n_c = 0.207 \) for \( l = 2, n_c = 0.138 \) for \( l = 3 \). For \( l = 1 \) the complete phase diagram is shown in Fig. 1. The lower region ( for \( U < -4 \) ) is characterized by only double occupied (solid circles) and empty (empty circles) sites so \( n = 0 \) and \( n_2 = n/2 \). For \( -4 < U < U(n_1) \) we have a mixed region, the ground state includes both finite densities of single electrons (spheres with dot center) and localized electron
pairs. These phases are superconducting, since the two particle correlation function \( \langle \eta_i^\dagger \eta_j \rangle \) (here \( \eta_j^\dagger = c_j^\dagger c_{j+} \)) exhibits ODLRO, i.e. \( \langle \eta_i^\dagger \eta_j \rangle \to 0 \) for \( |i-j| \to \infty \). At \( n > n_\text{c} \), a curve \( U(n_\text{c}) \) separates this phase on Luttinger liquid state at \(-4 < U < U(n_\text{c})\) and strongly interacting Luttinger liquid state at \( U(n_\text{c}) < U < U(n_1)\). The strongly interacting Luttinger liquid state is denoted as SILL in the figures. Note, that strongly interacting Luttinger liquid state is realized at largest values of a repulsive on-site Coulomb interaction and a high electron density. Comparing the calculations for different \( l \) we can conclude that a hard-core repulsive interaction increases a region of the coexistence of strongly interacting Luttinger liquid and superconducting phase due to both a larger \( U_c \) and smaller \( n_\text{c} \). For \( U > U(n_1) \) and \( n < n_\text{max} \) the ground state coexists of singly occupied and empty sites; dotted lines separate a metallic phase (at \( n < n_\text{max} \)) and an insulator phase (at \( n \geq n_\text{max} \)) with a gap \( \Delta \varepsilon = U - U_c \).

An exact solution of the problem enables to study the role of the exchange interaction on the behavior of a strongly interacted electron system. Let us consider a transformation of the exact ground-state phase diagram for \( J = 1 \), we restrict our consideration the case \( n \leq n_0 \). \( \Theta \) increases monotonically from \( \frac{1}{8} \) to \( \frac{(3+2l^2)}{12}[1 - \frac{3}{(3+2l^2)^2}] \) with the \( n_1 \) density. We should solve equation \( \Theta(n_\text{c}) = 1 \) numerically calculating the dressed charge as a function of the electron density \( n_1 \) for arbitrary \( l \); for example \( n_\text{c} = 0.348 \) for \( l = 1 \), \( n_\text{c} = 0.192 \) for \( l = 2 \), \( n_\text{c} = 0.131 \) for \( l = 3 \), \( n_\text{c} = 0.1 \) for \( l = 4 \). According to the numerical results obtained the critical density \( n_\text{c} \) is less than \( n_0 \) for \( l = 2 \) the ground state phase diagram is given in Fig. 2. All electron states: empty, single occupied and doubly occupied sites are presented simultaneously in a mixed region (a closed region in figure 2). For \( n_\text{c} < n < n_0 \) two branches of curves separate Luttinger liquid state and strongly interacting Luttinger liquid, that is realized between these branches. Comparing the phase diagrams for \( J = 1 \) (Fig. 3) and \( J = 0 \) (Fig. 1) calculated for the same value of \( l \) we can conclude that the exchange interaction decreases the region of the coexistence of the superconducting phase and strongly interacting Luttinger liquid state \( (n_\text{c} \text{ and } U_c \text{ decrease slightly}) \). \( U_c \) increases with an increasing of hard-core radius.

In summary, we have presented a soluble generalization of the Lai-Sutherland model, having the nontrivial Luttinger liquid behavior. The exact solution was obtained by means of the nested Bethe Ansatz. We have derived the exact ground-state phase diagram; the latter exhibits an unusual phase state in which superconducting phase and strongly interacting Luttinger liquid state coexist. This phase is realized at high electron density and positive values of the on-site Coulomb interaction. The maximum critical value \( U_c \) realized in the model is higher than that of all other exactly solvable models. This is important because higher values of \( U_c \) expands the region of coexistence of superconducting phase and strongly interacting Luttinger liquid state. It has been shown that the presence of the Fermi level is not necessary for realization of superconducting phase. The results of calculations of one dimensional models do not allow direct application
to the real 2D and 3D systems. Nevertheless one can assume that real high-Tc superconductors belong to the family of strongly interacting Luttinger liquid described above.
