Abbreviations: ANOVA, analysis of variance; Atg7−/− cell, beta cell-specific Atg7-deficient; AUC, area-under the curve; DPP-4, dipeptidyl peptidase-4; ELISA, enzyme-linked immunosorbent assay; ER, endoplasmic reticulum; GLP-1, glucagon-like peptide-1; GSIS, glucose-stimulated insulin secretion; KRB, Krebs-Ringer Bicarbonate; HG, high glucose; IHC, immunohistochemical; IPGTT, intraperitoneal glucose tolerance test; ITT, insulin tolerance test; LG, low glucose; NS, no significant difference; RT-PCR, real time polymerase chain reaction; T2DM, type 2 diabetes mellitus

Incretin-based therapy such as GLP-1 receptor agonists and DPP-4 inhibitors for type 2 diabetes mellitus is characterized by glucose-dependent insulin secretion and glucose-inhibited glucagon secretion. Recently, autophagy deficiency in islet β cells has been shown to contribute to the pathogenesis of type 2 diabetes mellitus however, with the role of incretin has not been established. To evaluate the role of autophagy in incretin effects, 8-week-old male β cell-specific Atg7 knockout (Atg7−/− cell) mice and wild-type mice were administered vildagliptin for 12 weeks. Vildagliptin treatment improved glucose intolerance and hypoinsulinemia; however, it failed to suppress serum glucagon levels after glucose loading in the Atg7−/− cell mice. Ex vivo glucose-induced glucagon suppression was also blunted in the islets from vildagliptin-treated Atg7−/− cell mice. The α cell mass was not affected by β cell autophagy deficiency or vildagliptin. However, glucagon mRNA expression was significantly increased by vildagliptin in the autophagy-deficient islets, and was significantly reduced by vildagliptin in wild-type islets. Pancreatic glucagon contents were not in agreement with the changes in mRNA expression, suggesting a dysregulation in glucagon translation and secretion. In vitro studies revealed that glucose-stimulated cAMP production was impaired in the autophagy-deficient islets exposed to exendin-4. Taken together, the results suggest that the constitutive autophagy in β cells could regulate incretin-induced glucagon expression and release in α cells, and that cAMP may play a role in this process.

Introduction

Pancreatic islets are composed of several hormone-releasing cell types, including α cells and β cells. It is known that different types of islet cells interact with each other via a paracrine mechanism.1 Glucagon-like peptide-1 (GLP-1), one of the incretin hormones, stimulates insulin secretion in β cells, inhibits glucagon release in α cells, and lowers blood glucose levels in a glucose-dependent manner.2 Currently, incretin-based therapies such as GLP-1 receptor agonists and dipeptidyl peptidase-4 (DPP-4) inhibitors, which inhibit GLP-1 degradation and prolong its effects, are important treatment regimens for type 2 diabetes mellitus (T2DM).3 In addition, incretin-based therapy has been reported to regenerate β cells and to inhibit β cell apoptosis in some animal models.2 However, it is unclear whether incretin-based therapy affects the α cell mass.4 A small human autopsy study described hyperplasia of pancreatic α cells in T2DM patients treated with incretin therapy.5 However, extensive preclinical studies in rodents and nonhuman primates failed to detect α cell hyperplasia and even reported a decrease in α cell mass as a result of incretin therapy,6-8 including vildagliptin,9,10 a DPP-4 inhibitor.

Autophagy is a lysosomal degradation pathway that is essential for cell survival, differentiation, development, homeostasis, and the control of cellular metabolism, including in pancreatic β cells. The β cell-specific autophagy-deficient mice by Atg7 deletion (Atg7Δβ cell mice) showed glucose intolerance and hypoinsulinemia. Decreased β cell function and mass were observed in the mice, and were associated with a distended endoplasmic reticulum (ER), suggesting ER stress and mitochondrial dysfunction in the β cells. Furthermore, autophagy deficiency was shown to contribute to β cell dysfunction and β cell loss in human T2DM. Therefore, it is important to consider the effects of autophagy deficiency in the management of T2DM. There is one report on the use of incretin therapy in Atg7Δβ cell mice. Exendin-4, a GLP-1 receptor agonist, decreased β cell death, increased insulin secretion, and improved glucose intolerance in Atg7Δβ cell mice. However, the influence on α cells, another target of GLP-1, was not described. Therefore, we evaluated the long-term effects of a DPP-4 inhibitor on α cell mass and function in β cell-specific autophagy-deficient mice, to further examine the role of β cell autophagy in incretin effects.

Results

Vildagliptin enhanced insulin secretion and improved glucose intolerance in Atg7Δβ cell mice

In the Atg7Δβ cell mice, body weights were slightly lower and fed blood glucose levels were higher than those of wild-type mice, regardless of treatment (p < 0.005; Fig. 1A and B). In each mouse genotype, the vildagliptin treatment did not affect these variables. However, according to the intraperitoneal glucose tolerance test (IPGTT), vildagliptin significantly reduced glucose intolerance in the Atg7Δβ cell mice (Fig. 1C and D). There was no difference in glucose tolerance by the vildagliptin treatment in wild-type mice. As previously reported, vildagliptin significantly increased fasting serum insulin levels in both genotypes (Fig. 1E).
Vildagliptin blunted glucose-induced glucagon suppression in Atg7−/− cell mice

Glucose loading significantly suppressed serum glucagon levels in both mouse genotypes (Fig. 2A). However, the glucose-induced glucagon suppression disappeared in the vildagliptintreated Atg7−/− cell mice. Next, glucose stimulation of isolated islets was done ex vivo (Fig. 2B). Vildagliptin induced significant glucagon suppression by high glucose in the wild-type islets, while it did not in the Atg7−/− cell islets. The glucagon suppression index calculated from the ex vivo study demonstrated different responses to vildagliptin between the genotypes (Fig. 2C).

Vildagliptin affected glucagon synthesis but not α cell mass in Atg7−/− cell mice

We assessed the α cell mass using point counting after immunohistochemical (IHC) staining for glucagon in pancreas sections (Fig. 3A). Morphologies, distributions, and masses of α cells were comparable regardless of genotypes or vildagliptin treatment (Fig. 3B). Quantitative real-time polymerase chain reaction (RT-PCR) with isolated islets demonstrated that mRNA expression levels of glucagon decreased in the wild-type islets while mRNA increased in the Atg7−/− cell islets after vildagliptin treatment (Fig. 3C). Changes in pancreatic glucagon contents by vildagliptin were opposite to the changes in glucagon transcripts in both mouse genotypes, although they were not significant (Fig. 3D).

Glucose-stimulated cAMP responses were blunted in Atg7−/− cell islets exposed to exendin-4 in vitro

Long-term administration of vildagliptin regulated α cell function to produce and secret glucagon in vivo. However, the cause of blunted glucose-induced glucagon suppression remains uncertain. Therefore, we examined GLP-1 signaling using in vitro exendin-4 treatments. Because cAMP is a key mediator of the GLP-1 pathway, we determined if the cAMP response correlated with autophagy status. Although high glucose was challenged in the presence of exendin-4, cAMP did not increase in the Atg7−/− cell islets, unlike in the wild-type islets (Fig. 4A). However, an increase of ATP by high glucose levels in the presence of exendin-4 was unaffected regardless of β cell autophagy status (Fig. 4B). Because cAMP is synthesized from ATP by adenylyl cyclase through the GLP-1 receptor, these findings suggested that GLP-1 signaling was impaired in the autophagy-deficient islets.

Discussion

In this study, and as previously reported, the effects of long-term vildagliptin treatment on glucose homeostasis of Atg7−/− cell mice was favorable, as shown by improved glucose tolerance from enhanced insulin secretion. However, the well-known incretin effect of glucose-induced glucagon suppression was abrogated (Fig. 2A–C). Therefore, we can infer that β cell autophagy has a role in the incretin effects on α cells.

Constitutive autophagy deficiency in β cells did not affect α cell function involving incretin. The expression of the glucagon transcript was increased by vildagliptin in the islets with autophagy-deficient β cells, contrary to in the wild-type islets (Fig. 3C). In contrast, pancreatic glucagon content was not increased...
by vildagliptin in Atg7<sup>−/−</sup> cell mice (Fig. 3D). In the wild-type mice, in spite of the suppressed mRNA expression by vildagliptin, pancreatic contents did not decrease. These findings can be interpreted as follows. First, translational processes might be impaired in the autophagy-deficient islets, which could reduce the increase of glucagon peptides. Second, glucagon secretory processes might not be adequately inhibited by vildagliptin in the autophagy-deficient islets, which could also contribute to the lack of an increase of pancreatic contents, along with no-decrease of serum glucagon levels by glucose stimulation (Fig. 2A). However, the discrepancy between glucagon mRNA levels and glucagon contents could have come from the experimental methods used. While glucagon mRNA levels were measured with isolated islets, glucagon contents were measured with whole pancreatic extracts. Comparable pancreatic weights (data not shown) and α cell masses (Fig. 3B) among the groups may have prevented erroneous results, but islet isolation procedures could have still affected the discrepancy. The effects of autophagy on incretin-stimulated glucagon production and secretion in the islets have not been previously reported, and the mechanisms require further verification.

Glucagon secretion is regulated by circulating insulin and glucose. Therefore, our in vivo observations must have been affected by the hyperglycemia present in the Atg7<sup>−/−</sup> cell mice, although the hyperglycemia was mild (Fig. 1B). Therefore, we performed in vitro experiments to evaluate the role of autophagy in the GLP-1 pathway, to exclude the effects of hyperglycemia. It is well-known that GLP-1 potentiates glucose-stimulated cAMP increases in β cells, and that this contributes to insulin secretion in a glucose-dependent manner. However, in the Atg7<sup>−/−</sup> cell islets, we did not observe the cAMP response to glucose stimulation in the presence of exendin-4 (Fig. 4A). Because we measured cAMP in whole islets, it was not possible to identify the cAMP response according to cell types. Although incretin induced cAMP in β cells and α cells via incretin receptors, most of the mouse islets were composed of β cells, therefore the cAMP response in the mouse islets represents the response in the autophagy-deficient β cells. Generation of ATP, the precursor of cAMP, was not be affected by autophagy status in β cells (Fig. 4B). This suggested that constitutive autophagy in β cells had a role in cAMP generation from ATP in response to GLP-1. The possible causes of impaired cAMP generation, including GLP-1 receptor

Figure 3. Effects of vildagliptin on the α cell mass and glucagon synthesis in Atg7<sup>−/−</sup> cell mice. (A) Pancreas sections were stained with the anti-glucagon antibody. Representative images of islets from control (left) and vildagliptin-treated (right) Atg7<sup>−/−</sup> cell mice are shown (scale bar, 100 μm). (B) The α cell mass was calculated by point counting (n = 4–5 in each group). (C) The mRNA expression of glucagon compared to that of GAPDH in the islets was assessed by quantitative RT-PCR (n > 6 in each group). (D) Pancreatic glucagon contents were measured from pancreatic extracts (n > 5 in each group). Student’s t tests were used between control and vildagliptin groups in each mouse genotype; NS indicates no significant difference.

Figure 4. Glucose-stimulated cAMP production by incretin was impaired in Atg7<sup>−/−</sup> cell islets. The Atg7<sup>−/−</sup> cell and wild-type islets were treated with or without 50 nM of exendin-4 in vitro for 2 h (n of experiments > 6), and then glucose stimulation was performed. Cellular cAMP (A), and ATP contents (B) were measured under low glucose (LG, 1.5 mM) or high glucose (HG, 15 mM), and adjusted by cellular protein. * indicates significant difference (p < 0.05) by paired t-tests between LG and HG. NS indicates no significant difference.
desensitization and adenylyl cyclase down-regulation could have been affected by autophagy deficiency.

One concern with the use of autophagy-deficient islets in this study is that they are insulin deficient. Glucagon secretion is closely regulated by insulin. However, according to Abe et al, exendin-4 increased glucagon-dependent insulin secretion in the same mouse model, suggesting that insulin response to incretin was preserved even in autophagy-deficient β cells. Therefore, we suggest that β cell-specific autophagy deficiency directly affects α cell function, although indirect insulin effects cannot be excluded completely by the current data.

A limitation of this study design is that there could be confounding effects by genetic modulation. First, RIP-Cre mice can show Cre expression in the brain, or human growth hormone minigenes could affect the experimental results. The lower body weights in the Arg72Δβ cell mice (Fig. 1A) are consistent with this possibility, although we did not study the diet. Second, the mixed background of the Balb/c mice could have affected islet function, despite the use of littermates.

In summary, we found that long-term vildagliptin treatment failed to suppress glucagon secretion after glucose loading in the Arg72Δβ cell mice in vivo and ex vivo, and was associated with changes in α cell function of glucagon production. Impaired cAMP responses and resultant changes in insulin around α cells may have contributed to these results. GLP-1 receptor agonists and DPP-4 inhibitors are known to inhibit glucagon secretion most likely via GLP-1 receptor–dependent stimulation of somatostatin secretion. A recent study reported that both insulin and somatostatin were required in glucose-inhibited glucagon secretion. Therefore, β cell autophagy may also have a role in somatostatin secretion. DPP-4 expression on the islet cell surface may also have influenced our results.

In conclusion, β cell autophagy is required for the incretin effects on cAMP generation and the glucagon suppression in response to glucose.

**Material and Methods**

**Animals**

Arg72Δβ mice (C57Bl/6J background) were from Professor Masaaki Komatsu, and were backcrossed with the Balb/c mouse strain. Mice with backcross over 3 were used as wild-type controls. Male mice were fed standard chow diets, and were randomized into control and vildagliptin groups at 8 weeks of age. In the vildagliptin group, vildagliptin was administered via drinking water for 12 weeks. The fed blood glucose levels and body weights were monitored weekly using a glucometer (One Touch, Johnson & Johnson, Milpitas, CA, USA) and standard scale, respectively.

All animal experiments were conducted in accordance with the institutional guidelines of Seoul National University Hospital.

**IPGTT and ITT**

After completion of the 12 week vildagliptin or vehicle administration at 20 weeks of age, IPGTT and ITT were performed. The ITT was performed after 6 h of fasting, with a 0.75 unit/kg (body weight) intraperitoneal insulin injection, followed by serial monitoring of blood glucose for 60 min. The IPGTT was performed after overnight fasting, with a 1 g/kg (body weight) intraperitoneal glucose injection, followed by serial glucose monitoring. During the IPGTT, serum was also obtained from retro-orbital blood samples to measure insulin (enzyme-linked immunosorbent assay (ELISA) kit, ALPCO, Salem, MA, USA) and glucagon concentrations (ELISA kit, R&D System Inc., Minneapolis, MN, USA).

**Ex vivo isolated islet experiments**

Pancreatic islets were isolated from overnight fasted mice using the collagenase digestion technique. For the glucose-regulated glucagon secretion assay, isolated pancreatic islets were starved in Krebs-Ringer bicarbonate (KRB) buffer containing 0.2% bovine serum albumin and 1.5 mM glucose for 1 h at 37°C. Then, the media was replaced with KRB containing 1.5 mM or 15 mM glucose. After a 1 h incubation, the supernatant was collected for the measurement of glucagon (ELISA kit, Sigma-Aldrich, St Louis, MO, USA), and cAMP (Cell Biolabs, Inc., San Diego, CA, USA). The suppression index for glucagon was calculated using the supernatant glucagon levels obtained from islets incubated in 15 mM glucose divided by the glucagon level from supernatant incubated in 1.5 mM glucose. Exendin-4 (Sigma-Aldrich), a GLP-1 receptor agonist, was added for 2 h in some in vitro experiments.

**Estimation of α cell mass**

The pancreas was embedded in paraffin and sectioned to a thickness of 4 μm. IHC staining was performed with the antimouse glucagon antibody (Sigma-Aldrich), and the α cell mass was then estimated by point counting. In brief, the point numbers of glucagon-stained areas were counted at a magnification of 400× using a 48-point grid. The relative α cell area was calculated by dividing the point number of the glucagon-stained area by the point number over the entire pancreatic tissue sample on the same section. Two sections, separate from each other by 20 μm, were used for the mean relative area determination. The average number of islets was 20 ± 10 per section. The α cell mass was then estimated by multiplying α cell relative area by the pancreas weight.

**Quantitative real-time polymerase chain reaction (RT-PCR) of glucagon mRNA**

Total RNA was isolated from the islets, and the cDNA was synthesized and amplified using the SYBR Premix Ex Taq polymerase (TaKaRa, Otsu, Japan). The quantitative RT-PCR was performed.
pancreatic hormones were extracted using a previously published method.28 ELISA was performed to measure the glucagon levels of the pancreatic extracts (R&D System, Inc.). The concentrations were normalized by pancreas weights.

Statistical analysis

All data are expressed as means ± standard error of the mean. A repeated measures analysis of variance (ANOVA) and subsequent post-hoc Tukey’s Honestly Significant Difference (HSD) test were used for serial changes in body weight and glucose levels (Fig. 1). Student’s t tests were employed to compare vildagliptin effects in the wild-type or in the knock-out groups. Paired t-tests were performed to evaluate glucagon, cAMP, and ATP responses to glucose stimulation. All analyses were performed using SPSS 14.0 for Windows (SPSS Inc., Chicago, IL, USA).

Acknowledgments

We are grateful to Professor Masaki Komatsu for the kind donation of Agt-7-floxed mice, and to Novartis for the supply of vildagliptin.

Disclosure of Potential Conflicts of Interest

No potential conflicts of interest were disclosed.
