Abstract

Based on the framework of consistent history theory, the quantum entangled history was proposed in 2015 and experimentally verified through temporal Greenberger-Horne-Zeilinger (GHZ) test with 3 time nodes in 2016. In this paper, we extend the temporal GHZ test to arbitrary time nodes and even system dimensions. Then, we define a witness to distinguish between the quantum entangled histories and the classical histories. The minimums of the witness for the classical histories are calculated for arbitrary number of time nodes and the system dimensions $2$ and $\infty$. It is found that the minimums of the witness for the classical histories is always larger than the quantum entangled histories minimum $-1$. Only when both the number of time nodes and system dimensions approach to infinity, the minimum of the witness for classical and quantum entangled histories are identical.

I. INTRODUCTION

Quantum entanglement, since proposed by Einstein, Podolsky and Rosen (EPR) [1] and further explored by Schrödinger [2] in 1935, has always been the focus of quantum physics realm. The EPR paradox revealed the conflict between quantum theory and local realism. Almost 30 years later, in 1964, John Bell first came up with the prototype of a family of inequalities, which were later called Bell inequality [3–5], to express certain limitation that every local classical hidden variable theory should follow up. Therefore, it could be used to distinguish the quantum theory from the local hidden variable theories [6]. Experimental verifications on Bell inequality lasted for 40 years, until the loophole-free experiments was performed in 2015 [7–9].

The widely accepted interpretation of quantum mechanics is the Copenhagen interpretation. However, one of the major problems with the interpretation is the unnatural collapsing of states when a quantum state is measured. Due to this concern, Griffiths brought up a different interpretation, which can give the same physical result as Copenhagen interpretation but without collapsing of states, called the consistent histories theory [10]. Under the framework of consistent histories theory, Frank Wilczek and Jordan Cotler defined a new concept quantum entangled histories [11], which are entanglement in time, other than entanglement in space. Later, they proposed a Bell test for entangled histories [12]. We should note that some previous literature studied temporal entanglement both theoretically [13–16] and experimentally [17]. They focused on the paradox emerging from entanglement induced by measurement and prediction by classical theory. However, the entangled history theory focuses on the intrinsic correlation in quantum dynamics.

In 2016, the quantum entangled history was experimentally verified through a temporal Greenberger-Horne-Zeilinger (GHZ) test [18, 19] for quantum entangled history state with 3 time nodes [20]. The classical stochastic processes were introduced as the representative of classical theories. A function $G$ was defined to distinguish quantum and classical theory. It was proved that for quantum theory, $G$ could approach $-1$ while the lower bound of $G$ for classical theory is $-\frac{1}{16}$. In the experiment, $G$ was measured of $-0.656$, which clearly showed that quantum entangled histories existed.

This paper aims to broaden the scope of temporal GHZ paradox from 3 time nodes to arbitrary nodes, and from dimension 2 (qubit) to arbitrary even (qudit). For the 2
dimensional system, we discuss a temporal GHZ-type test with arbitrary time nodes. We define a witness and prove that the boundaries between classical and quantum entangled histories expectations exist. We find exact boundary formula for arbitrary time nodes $m$. Inspired by Ref. [21], we construct the temporal GHZ-type test for high dimensions (qudit). The boundaries between classical and quantum expectations are also proved to be existed and calculated. We specifically analyze the behavior of minimum when the dimension is 2 and $\infty$. We find that when the dimension and number of time nodes tend to infinity, the minimum will be approached to $-1$. Therefore, the classical and quantum predictions are indistinguishable.

This paper is organized as follows. Section II focuses on the background knowledge and mathematical framework of entangled history. Section III gives a brief review on the GHZ type tests in space. Section IV discuss the temporal GHZ-type tests. The boundaries between classical and quantum entangled histories predictions are calculated and proved. In the last section, we give a brief summary and prospect.

II. THEORETICAL BASIS FOR ENTANGLED HISTORIES

The introduction of main mathematical formulation of entangled history theory mainly follows the structure of [11], where the motivation of entangled history theory is discussed more in detail. The Hilbert space of history states is the vector space which we will focus on. It is defined as the tensor product of several ordinary Hilbert spaces, each simply the Hilbert space of the system at a particular time $t_i$. An issue worthy of attention is that the time sequence is from later to former, i.e., the history Hilbert space should be written as follows [10, 11]:

$$\mathcal{H} := \mathcal{H}_{t_n} \odot \mathcal{H}_{t_{n-1}} \odot \cdots \odot \mathcal{H}_{t_1}, \quad t_n > t_{n-1} > \cdots > t_1$$

in which the special notation $\odot$ is used to represent tensor product in time domain as in [12] and reserve the notation of $\otimes$ to represent tensor product in space domain.

In this paper, the Hilbert space of the history of a sequence of discrete moments, each connected by a bridging operator, is concerned. The bridging operator is denoted $T(t_j, t_i)$ for mapping the Hilbert space $\mathcal{H}_{t_i}$ to $\mathcal{H}_{t_j}$, and is determined using the Schrödinger’s Equation.
The history states are defined as:

$$|\Psi\rangle = P_{t_n}^{i_n} \otimes \cdots \otimes P_{t_1}^{i_1}$$  \hspace{1cm} (2)

in which $P_{t_k}^{i_k}$ is some projector in $H_{t_k}$. Each $t_k$ is called a time node.

Now consider a GHZ history state

$$|GHZ\rangle = \frac{1}{\sqrt{2}}(|0\rangle \otimes |0\rangle \otimes |0\rangle - |1\rangle \otimes |1\rangle \otimes |1\rangle)$$  \hspace{1cm} (3)

in which $[i] = |i\rangle \langle i|$. An important characteristic of the measurement of history states is that they must be constructed and measured spontaneously. An example may be the measurement of the GHZ history state shown in Ref. \[22\] that includes the protocol for measuring history states. Using the formalism of Ref. \[22\], we can find the expectation of a temporal observable, $Q$, in the same way we calculate the expectation of a normal observable $Q'$, namely $\langle \psi | Q | \psi \rangle$. The expectation of the temporal observable is $\langle i_1 i_2 \ldots i_n | Q | i_1 i_2 \ldots i_n \rangle$, in which $[i_1 i_2 \ldots i_n] = P_{t_n}^{i_n} \otimes \cdots \otimes P_{t_1}^{i_1}$. If a GHZ state $|GHZ\rangle = \frac{1}{\sqrt{2}}(|000\rangle - |111\rangle)$ is constructed and measured in the $|000\rangle, |001\rangle \ldots$ basis, probability amplitudes $\langle i j k | GHZ \rangle = \frac{1}{\sqrt{2}}(\langle i |0\rangle \langle j |0\rangle \langle k |0\rangle - \langle i |1\rangle \langle j |1\rangle \langle k |1\rangle)$ are obtained. In experiment, the measurement needs auxiliary qubits or qudits to record the information of the system.

The probability of some measurement outcome from a history state is identical to the probability of measuring a normal state and get the same results, namely, the probability of getting outcomes $(i, j, k)$ is also $\langle i j k | GHZ \rangle$. Due to this property, whenever calculation of the expectation for a history state is needed, we use the inner product of bra and ket as usual.

III. GHZ-TYPE ENTANGLEMENT IN SPACE

The GHZ-type entanglement is one of the most well-studied type of entanglement since it demonstrates distinctive results predicted by classical local theories and quantum theories \[18, 19\]. In this section, the current results and construction of several others are summarized. These examples in space domain will provide significant support and a general framework to our discussion about the GHZ-type tests in time domain. From this section, we omit any notation of tensor product in time.
A. Original GHZ construction

The original GHZ state[18, 19] is a three-partite two-dimensional entangled state:

\[ |GHZ\rangle = \frac{1}{\sqrt{2}}(|000\rangle - |111\rangle) \]  

Witnesses denoted \( Q_1 = X_1 X_2 X_3 \), \( Q_2 = X_1 Y_2 Y_3 \), \( Q_3 = Y_1 X_2 Y_3 \), \( Q_4 = Y_1 Y_2 X_3 \) are used, where \( X_i \) or \( Y_i \) is the pauli matrix \( X \) in the \( i \)th Hilbert space.

\[ \langle X_1 X_2 X_3 \rangle = -1, \langle X_1 Y_2 Y_3 \rangle = 1, \langle Y_1 X_2 Y_3 \rangle = 1, \langle Y_1 Y_2 X_3 \rangle = 1. \]  

\(|GHZ\rangle\) is a common eigenvector of all four operators. An observable \( G = X_1 X_2 X_3 Y_1 Y_2 Y_3 Y_1 Y_2 X_3 \) is measured. Hence, \( G_{qm} = \langle X_1 X_2 X_3 \rangle \langle X_1 Y_2 Y_3 \rangle \langle Y_1 X_2 Y_3 \rangle \langle Y_1 Y_2 X_3 \rangle = -1 \) in quantum theory. As \(|GHZ\rangle\) is a common eigenvector, \( G_{qm} = \langle X_1 X_2 X_3 X_1 Y_2 Y_3 Y_1 X_2 Y_3 Y_1 Y_2 X_3 \rangle \). If \( G \) is considered in classical local theory, the incommutativity of the operators is lost, and thus \( G_c = \langle \prod Q_i \rangle = (X_1 X_2 X_3 Y_1 Y_2 Y_3)^2 = 1 \) because each operator is treated like a random variable with value ±1. This is a distinctive difference.

An important advantage of GHZ-type entanglement is that the prediction of quantum mechanics and classical stochastic theory is determined and separated. Hence, it is easier for the experiments to detect GHZ-type entanglement.

B. Extension to higher dimension and arbitrary number of particles

When the GHZ-type entanglement is extended to higher dimensions, we aim to preserve the advantages of GHZ paradox: the quantum prediction and the classical prediction are significantly separated from each other and the witnesses are all products of \( X \), \( Y \) and \( Z \),
the generators of the Heisenberg group. The operators $X$, $Y$ and $Z$ are defined as follows

$$X = \sum_{k=1}^{d-1} \langle (k+1) \mod d \rangle \langle k |$$

$$Y = \sum_{k=1}^{d-1} e^{2\pi i k/d} \langle (k-1) \mod d \rangle \langle k |$$

$$Z = \sum_{k=1}^{d-1} e^{2\pi i k/d} |k \rangle \langle k |$$

Previously, the genuine GHZ paradoxes are constructed for even dimensions and arbitrary number of particles [21, 23, 24]. They constructed special graphs called GHZ graphs whose adjacency matrix and vertex operators give rise to a GHZ-type paradox. This study provides us with an ideal model of entangled histories.

We have found no construction of an odd dimension GHZ paradox using the same definition as ours in previous literature. In these papers [21, 25], the construction is only given for even dimension. A proof that there is no GHZ paradox in the framework of odd dimension is given in Appendix A. However, if we use another definition of operators, the GHZ paradoxes in odd dimension can be defined, as shown in Ref. [26–28]. However, their definition needs special calculation for each pair of particle number and dimension in order to control the phases of eigenvalues to reach a paradox. The construction for the GHZ paradoxes in odd dimensions is state-dependent.

**IV. TEMPORAL GHZ TESTS WITH ARBITRARY TIME NODES AND DIMENSIONS**

A complete construction of entanglement witnesses for GHZ states in space has been summarized in the last section. In this section, we explore GHZ-type entangled histories for arbitrary time nodes and dimensions. We construct the GHZ-type tests for entangled history states. Similar as Ref. [20], we find that there are boundaries between entangled histories and the classical histories.

Similarly as GHZ test in space, we can define an observable $G$ to distinguish quantum entangled histories and classical states. The quantum prediction of $G$ for entangled GHZ-type history state, e.g. Eq. (3) is always $-1$. In classical theory, each time nodes in histories
are correlated in a non-local way, rather than locally related in GHZ states in space. Hence, instead of taking $\langle \prod Q_i \rangle$ for classical mechanics, the observable $\prod \langle Q_i \rangle$ is taken to signify the reduced reliability of $Q_i$ on each other. Note that $\prod Q_i$ is still 1.

Hence, each possible combination of values of $Q_i$ - a timeline - is taken to be $a_j = (Q_{ij})$, in which $Q_{ij}$ is the $i$th outcome of the combination $a_j$. Suppose the probability for $a_j$ is $p_j$. Then the quantity $\prod \langle Q_i \rangle$ can be expressed as:

$$E_t(n, d) = \prod_i (\sum_j Q_{ij}p_j) \quad (7)$$

in which $n$ is the number of witnesses and $d$ is the dimension of the Hilbert space. Now, the problem reduces to finding the boundary for $E_t(n, d)$. Also, we denote the number of time nodes $m$. In general, $n = m + 1$. Hence, $n$ grows when $m$ increases.

### A. Temporal GHZ test for Qubits

In Ref. [20], the minimum of $E_t(4, 2)$ was calculated and proved. This corresponded to a qubit system with 3 time nodes. In the paper, they proved that $E_t(4, 2)$ has a minimum of $-\frac{1}{16}$. However, the method in Ref. [20] cannot easily extend to arbitrary time nodes $m \geq 3$.

Here we consider an entangled GHZ-type history state with number of time nodes $m \geq 3$. It is easily found that here the number of witnesses $n = m + 1$. In this formalism, there would be $2^n$ different history timelines with outcome 1 or $-1$ for the $n$ measurements, or witnesses. One very crucial issue is that if we multiply all the outcomes of a timeline, the result should be 1. In mathematical form, it is:

$$\prod_i Q_{ij} = 1 \quad (8)$$

Because changing the last outcome from 1 to $-1$ or $-1$ to 1 changes the sign of the product, it can be concluded that there are $2^{n-1}$ possible outcomes.

Suppose outcome $j$ has a probability $p_j$ assigned to it. Then the classical expectation in
time domain, can be expressed as

\[ E_t = \prod_{i=1}^{n} \left( \sum_{j=1}^{2^{n-1}} Q_{ij} p_j \right) \] (9)

This is a polynomial for \( p_j \) with the constraint that \( \sum_j p_j = 1 \).

We have to find the minimum for \( E_t \) to confirm that it is indeed separated from quantum outcomes. In fact, the ultimate result is

\[ E_t(n, d) \in \left[ -\left(1 - \frac{2}{n}\right)^n, 1 \right] \] (10)

The detailed calculation can be found in Appendix B.

The importance of the minimum lies in two aspects. First, surprisingly, the minimum is not reached in a maximally mixed timeline, in which each of the timeline has the same probability. Furthermore, the combination which generates the minimum is unsymmetrical. Second, as shown in Fig. [1], the lower bound is not \(-1\) when \( n \to +\infty \). In fact, \( \lim_{n \to +\infty} E_t(n, 2)_{\min} = -e^{-2} \), which is larger than \(-1\). Hence, a gap is observed between the quantum prediction and classical prediction. For \( n = 4, d = 2 \), the GHZ-type test for entangled histories was performed with single photon experiment [20]. The quantum and classical predictions gap we proved here makes the GHZ-type entangled histories tests for arbitrary time nodes possible in experiment.

### B. Estimations for higher dimensions

In higher dimensions, by the construction of witnesses, \( n = m + 1 \). \( Q_{ij} \) takes the positive powers of \( \exp(2\pi i/d) \). \( E_t \) should be real while each sum in \( j \) may not be real. This generates a substantial problem for calculating \( E_t \) for \( d \leq 4 \) since there is no clear and feasible way to calculate the argument of \( E_t \). Furthermore, since \( \epsilon^k \) is discrete on the unit circle, we cannot use analytic methods if \( d \neq \infty \). These are the main difficulties in calculating.

However, the minimum of \( E_t(n, \infty) \) can be calculated. Since the phase could be set as continuous when \( n \to \infty \), the optimization is possible. The main idea of calculation is to find the deviation of the phase between entries of the timelines and the ultimate expectations of the witnesses. The deviations conform to some restraints, as shown in Appendix C, we
FIG. 1: The boundaries $E_t(n, 2)$ ($E_t(n, \infty)$) between GHZ-type entangled histories and classical histories for Hilbert space dimension 2 ($\infty$) and witness number $n$. $E_t(n, \infty)$ will approach $-1$ when $n$ approaches $\infty$.

find out that under the restraint the minimum is $-(\cos \pi/n)^n$. Also, the construction of the situation which generates the minimum requires that $n$ can divide $d$. Hence the minimum is reached for infinite times for fixed $n$ when we increase $d$. There will be a fluctuating pattern, while the deviation gradually decreases when $d$ is increased. The Fig. shows the minimum of $E_t(n, \infty)$ with respect to the number of witnesses $n$. It is found that, the boundaries for $d$ approaching to $\infty$ is much lower than the boundaries of $d = 2$ for every $n$. Besides, we can see that when $n \to \infty$, the minimum of $E_t(n, \infty)$ becomes $-1$. In other words, the quantum and classical predictions are mixed under this condition.

V. CONCLUSION AND PROSPECT

In this paper, we analyzed the GHZ-type entangled histories for arbitrary time nodes and dimensions. In particular, the case of $d = 2$ and $d = \infty$, are explored. We introduced classical correlations in time which give rise to an observable called $E_t(n, d)$. We prove respectively that the minimum of $E_t$ for $d = 2$ and $d = \infty$ are $-(1 - \frac{2}{n})^n$ and $-(\cos \frac{\pi}{n})^n$. They are both larger than the quantum prediction $-1$ for finite number of time nodes.
Moreover, there is an interesting phenomenon. Usually if we increase the dimension of Hilbert space $d$ to infinity, the quantum system would tend to behave in a classical way. However, in GHZ-type tests for entangled histories, even if $d = \infty$, there is still a huge gap between classical and quantum predictions for finite $m$. Only if we increase both $d$ and $m$ (with $n$) to infinity, which means both system dimensions and time are continuous, the predictions of both quantum and classical theories are indistinguishable. Though there is no dissipating channel being introduced, the mixture of quantum and classical predictions is simultaneous.

This phenomenon means that when $d$ is infinite, though the quantum system is similar to a complex classical system, there are still fundamental differences between quantum and classical correlation. For small $n$, if we observed a measurement outcome lower than the bound given, we can conclude device-independently that there is indeed quantum entanglement, even in time. We have not proved the minimum of $E_t(n,d)$ for all combinations of $n$ and $d$. Further calculation will help us understand how the dimension of the system and the number of time nodes change the boundaries between quantum entangled and classical histories. Besides, it may reveal the deep quantum correlation patterns between space and time.

In order to experimentally test the theory of the present work, beside the single photon experiments [18], we may use the NMR quantum simulator [29], the trapped ions [30], the graphene [31], or the optically trapped nano-particles [32, 33]. This work may stimulate further studies. For example, in future we may investigate the entangled histories for living object [34], experimentally testing the genuine entangled histories without sharing references [35], etc.

Appendix A: No GHZ paradox in odd dimensions

First, it can be observed that in the GHZ paradox, the quantum expectation has to be $-1$ because the $d$th power of some random variable is used to generate the certain result of 1 in classical mechanics. As the GHZ state constructed has to be an eigenvector of the witnesses with real eigenvalues, one of the eigenvalues must be $-1$. The reason is that $X$, $Y$ and $Z$ are all unitary operators, thus their tensor product must be unitary, and unitary operators have eigenvalues with module 1.

Thus, it remains to show that with the operators defined above, we can not generate any eigenvalue of $-1$.

$X$, $Y$ and $Z$ all have the spectrum of $S = \{ e^n| n \in \mathbb{Z} \}$ with $\epsilon = e^{2\pi i/d}$. On each sub-Hilbert space $X$, $Y$ or $Z$ or their arbitrary product is applied. A basis of the eigenspaces is taken to form the basis for the qudit with eigenvalue lying in $S$. Some of the eigenvalues might degenerate. Taking tensor product for each sub-Hilbert space, a basis for the entire Hilbert space is formed. Dividing it into the eigenvectors of the complete tensor product of $X$, $Y$ and $Z$ defined on each sub-Hilbert space, the eigenvalues still lie in $S$ as arbitrary products of the operators have order $d$.

However, as $d$ is odd, $-1 \notin S$. This completes the proof.

If we consider the definition of operators in these papers [26–28], we observe that the eigenvalues of the operators are not in $S$ defined above. The GHZ paradoxes can be constructed under this stated dependent method.

Appendix B: GHZ Test for quibits with arbitrary number of time nodes

We want to prove the conjecture that

$$(E_t)_{\text{min}} = -\left(\frac{n-2}{n}\right)^n$$

(11)

The proof is as follows:
Proof. First, a solution is given to generated the desired outcome:

\[
1, 1, 1, \ldots, 1
\]
\[
-1, -1, 1, \ldots, 1
\]
\[
-1, 1, -1, \ldots, 1
\]
\[
\vdots
\]
\[
-1, 1, 1, \cdots -1
\]

Choose these \( p_j \) to be \( \frac{1}{n} \) and others to be 0, this situation yields the value \(-\left(\frac{n-2}{n}\right)^n\).

Change the sign of \( Q_{ij} \) when \( i = 1 \) and obtain \( Q'_{ij} \). The corresponding \( E'_t \) is

\[
E'_t = \prod_{i=1}^{n} \left( \sum_{j=1}^{2^{n-1}} Q'_{ij}p_j \right)
\]

also

\[
(E_t)_{min} = -(E'_t)_{max}
\]

We use the Arithmetic-Geometric Average Inequality to get

\[
(E'_t) \leq \left( \frac{\sum_{i=1}^{2^{n-1}} d_jp_j}{n} \right)^n
\]

in which

\[
d_j = \sum_{j=1}^{m} Q'_{ij}
\]

More attention should be paid here in order to demonstrate that the inequality can be used. The inequality demands that every term \( \left\{ \sum_{j=1}^{2^{n-1}} Q'_{ij}p_j \right\} \) must be larger than or equal to 0, which is not necessarily the case here. However there is a simple argument that helps us get out of this. If the product is negative, the inequality fails, but it is obviously less than \( \left(\frac{n-2}{n}\right)^n \) and this situation should be ignored in search for the maximum. If the product is positive, there must be an even number of negative signs. \(-1\) is multiplied on each of the previously negative sums. The whole product is the same.

But this time,

\[
|d_j|_{max} = n - 2
\]
since
\[ |d_j|_{\text{max}} \leq n \]  \hspace{1cm} (18)

but for the equality to hold, all \( Q'_{ij} = 1 \) or \( Q'_{ij} = -1 \), but \( Q'_{ij} \) cannot be all the same since
\[ \prod_j Q'_{ij} = -\prod_j Q_{ij} = -1. \] The maximum is not reachable. \(|d_j|\) is an even number because \( n \) is even. However, when we choose \( Q'_{i1} = (-1, 1, 1, \ldots, 1) \)

\[ |d_1| = n - 2 \]  \hspace{1cm} (19)

which is the largest even number less than \( n \). So the maximum is proven.

Thus
\[ \left( \frac{\sum_{i=1}^{n-1} d_j p_j}{n} \right)^n \leq \left( \frac{|d_j|_{\text{max}}}{n} \right)^n = \left( \frac{n-2}{n} \right)^n \]  \hspace{1cm} (20)

So
\[ (E_t)_{\text{min}} = -(E'_t)_{\text{max}} = -\left( \frac{n-2}{n} \right)^n \]  \hspace{1cm} (21)

Similarly, the situation of taking equalities in the inequalities is verified, and the solution constructed meets all the standards.

The minimal value reached by increasing \( n \) to infinity would be
\[ \lim_{n \to +\infty} -\left( \frac{n-2}{n} \right)^n = -e^{-2}. \]  \hspace{1cm} (22)

**Appendix C: Minimum for** \( E_t(n, \infty) \) **and** \( E_t(n, kn) \)

**Proof.** Since \( d = \infty \), \( Q_{ij} \) can be any complex number on the unit circle. Suppose \( p_j \) is 0 for all but finite \( j \) to simplify the situation. We want \( E_t(n, \infty) \) to be as negative as possible; to do that, consider each term of \( E_t \). Take a combination of \( Q_{ij} \) and \( p_j \) which satisfy the restraints. Suppose \( a_i = \sum_j Q_{ij} p_j = r_i \exp(i\alpha_i) \). To make \( E_t \) negative it is required that \( \sum_i \alpha_i = \pi + 2k\pi, k \in \mathbb{Z} \). Now suppose \( Q_{ij} = \exp(i\alpha_{ij}) \) and \( \epsilon_{ij} \mod \alpha_{ij} - \alpha_i \). Now the restraint that \( \prod_i Q_{ij} = 1 \) becomes \( \sum_i \epsilon_{ij} = \pi + 2k\pi, k \in \mathbb{Z} \). Also \( \epsilon_{ij} \in [-\pi, \pi] \). The expression for \( E_t \) becomes
\[ E_t = -\prod_i (\cos \epsilon_{ij} p_j) \]  \hspace{1cm} (23)
Now $E_t' = \prod_i (\sum_j \cos \epsilon_{ij} p_j) = \prod_i b_i$ should be considered; it should be as large as possible. Eliminate all the possibilities that $E_t'$ are negative, similar to the process in Appendix B, since the minimum of $E_t'$ - which correspond to the maximum of $E_t$ - is $-1$. If $E_t'$ is positive, multiply each negative $b_i$ by $-1$ which would not change the value of $E_t'$ and still preserving the restraints. Now that each $b_i$ of $E_t'$ is positive, the arithmetic-geometric inequality can be applied:

$$E_t' = \prod_i (\sum_j \cos \epsilon_{ij} p_j) \leq \left( \frac{\sum_j p_j \sum_i \cos \epsilon_{ij}}{n} \right)^n \leq \left( |\sum_i \cos \epsilon_{ij}|_{max}/n \right)^n$$

(24)

which increases when $|\sum_i \cos \epsilon_{ij}|$ increases. Now the Lagrangian multiplier method with restraint is applied. This is the most significant difference of the case $d = \infty$ with the cases $d < \infty$. The choice of $Q_{ij}$ is continuous, rather than discrete. When $d$ is finite, the choice of possible timelines must yield to a transcendental equation, which greatly increases the difficulty of the problem. However, in the case of $d = \infty$, it can be reached that $|\sum_i \cos \epsilon_{ij}| \leq n(\cos \frac{\pi}{n})$ when $n$ is even. When $n$ is odd, the maximum is $n$ but this requires $\epsilon_{ij} = \pi$ which is not possible in physics. The second maximum is $n(\cos \frac{\pi}{n})$. Hence the conclusion is

$$E_t(n, \infty) \geq -(\cos \frac{\pi}{n})^n$$

(25)

It is reached when $p_1 = p_2 = \frac{1}{2}$, $Q_{1j} = 1$, $Q_{2j} = \exp(2\pi i/n)$. Also, when $n$ goes to infinity, $E_t(\infty, \infty) = -1$, which confirms our result.

Notice that the same minimum can be reached when $d = kn$ with $k$ a positive integer. We currently do not know about the behavior when $d \neq kn$ but a good guess would be that the minimum is reached when the solution is closest to the desired situation of minimum.
