ABSTRACT

Chemical Cartography, or mapping, of our Galaxy has the potential to fully transform our view of its structure and formation. In this work, we use chemical cartography to explore the metallicity distribution of OBAF-type disk stars from the LAMOST survey and a complementary sample of disk giant stars from Gaia DR3. We use these samples to constrain the radial and vertical metallicity gradients across the Galactic disk. We also explore whether there are detectable azimuthal variations in the metallicity distribution on top of the radial gradient. For the OBAF-type star sample from LAMOST, we find a radial metallicity gradient of ∆[Fe/H]/∆R ∼ −0.078 ± 0.001 dex/kpc in the plane of the disk and a vertical metallicity gradient of ∆[Fe/H]/∆Z ∼ −0.15 ± 0.01 dex/kpc in the solar neighborhood. The radial gradient becomes shallower with increasing vertical height while the vertical gradient becomes shallower with increasing Galactocentric radius, consistent with other studies. We also find detectable spatially-dependent azimuthal variations on top of the radial metallicity gradient at the level of ∼0.10 dex. Interestingly, the azimuthal variations appear close to the Galactic spiral arms in one dataset (Gaia DR3) but not the other (LAMOST). These results suggest that there is azimuthal structure in the Galactic metallicity distribution and that in some cases it is co-located with spiral arms.

Key words: Galaxy: disc, Galaxy: abundances, stars: abundances

1 INTRODUCTION

Understanding the formation, assembly, and evolution of galaxies across the universe is a key goal of astrophysics. To this end, the chemical, dynamical, and spatial properties of the constituent stars of galaxies are key tracers of the physics process that govern galaxy formation. Our own Galaxy represents an excellent laboratory for understanding galaxy formation and assembly because it is one of the few systems where we can (and have) obtain(ed) high-precision positions, velocities, kinematics, and chemical abundances for millions of stars. With these data, there has been a large breadth of literature on the chemical and dynamical nature for a large number of stars in our Galaxy, which has been used to infer how our Galaxy came to be. There has also been an explosion in our understanding of the distribution of stars and their properties across the Galaxy that has been facilitated by an industrial revolution in stellar spectroscopy. These data have enabled chemical cartography, or mapping, of the Milky Way through its stars (e.g., Hayden et al. 2015). One of result from chemical cartographic studies, which confirmed earlier work (e.g., Mayor 1976), is that both global metallicity, and other chemical abundances, have spatial variations across the Milky Way’s disk in the form of gradients (e.g., Boeche et al. 2013a; Cunha et al. 2016). These gradients have enabled us to not only learn about the structure of the Galaxy but have also provided key insights to its ‘inside-out’ formation history.

It has been shown (e.g., Andrievsky et al. 2002; Hou et al. 2002; Friel et al. 2002; Nordström et al. 2004; Allende Prieto et al. 2006; Lemarie et al. 2008; Magrini et al. 2009; Wu et al. 2009; Pedicelli et al. 2009; Friel et al. 2010; Ruchti et al. 2011; Luck & Lambert 2011; Bilir et al. 2012; Boeche et al. 2013b, 2014; Recio-Blanco et al. 2014; Mikolaitis et al. 2014; Plewne et al. 2015; Xiang et al. 2015a; Jacobson et al. 2016; Cunha et al. 2016; Onal Taş et al. 2016; Netopil et al. 2016; Yan et al. 2019; Gaia Collaboration et al. 2022b, and references therein) that the Milky Way’s disk (whether thick or thin), has a negative radial metallicity gradient such that the inner Galaxy (where the Galacticocentr...
centric radius, \( R \), is less than the solar value) is, on average, more metal-rich compared to the outer disk (where \( R \geq 8.27 \text{kpc} \)). This negative radial metallicity gradient ranges from \(-0.10 < \Delta\text{[Fe/H]}/\Delta R < 0.00\) dex/kpc in the Galactic plane (e.g. Özal Taş et al. 2016, and references therein) depending on the tracer population and survey volume. The negative radial metallicity gradient in the Galactic disk was strong evidence that the Galactic disk must have formed in an ‘inside-out’ manner (e.g., Frankel et al. 2019, and references therein), whereby the inner Galaxy formed early and fast and at later times the outer Galaxy formed. In addition to the radial metallicity gradient, many studies (e.g. Bar-Tabažić et al. 2003; Karaali et al. 2003; Allende Prieto et al. 2006; Soubiran et al. 2008; Yaz & Karaali 2010; Ruchti et al. 2011; Kordopatis et al. 2011; Chen et al. 2011; Bilir et al. 2012; Hayden et al. 2014; Bergemann et al. 2014; Boeche et al. 2014; Huang et al. 2015; Plevne et al. 2015; Xiang et al. 2015a; Yan et al. 2019; Nandakumar et al. 2020; Gaia Collaboration et al. 2022b, and references therein) have also found that the Galactic disk has a negative absolute vertical metallicity gradient. This gradient ranges between –0.25 < \( \Delta\text{[Fe/H]}/\Delta Z \) < –0.10 dex/kpc. Thus as the tracer population of stars gets further above (or below) the Galactic mid-plane, the average metallicity decreases. The size of the vertical gradient varies significantly with Galactocentric radius, becoming smaller in the outer Galaxy compared to the inner Galaxy (e.g., Özal Taş et al. 2016, and references therein).

The fact that there are radial and vertical metallicity gradients observed in the Galactic disk is established at this point, though there are some slight disagreements about the size of those gradients across the literature, likely related to the different samples/tracers used and volumes probed. That said, one area that requires more attention is to quantify whether there are azimuthal variations on top of the radial metallicity gradient. These azimuthal variations could arise by secular processes (e.g. Di Matteo et al. 2013; Khoperskov et al. 2018; Fragkoudi et al. 2018; Wheeler et al. 2021; Bellardini et al. 2022; Filion et al. 2023) or stellar migration due to tidal interactions between the Galactic disk and a Sagittarius-like dwarf galaxy (e.g. Carr et al. 2022). It may even be expected that azimuthal variations in metallicity could track along the spiral arms (e.g., Khoperskov & Gerhard 2021; Poggio et al. 2022). Additionally, azimuthal variation in the radial metallicity gradient (and thus distribution) have also been observed in other Galaxies (e.g., Hwang et al. 2019). However, the presence (or lack thereof) and size of azimuthal variations in the metallicity gradients observed in our own Galaxy has been not well explored.

Therefore, in this paper, we present the radial (\( \Delta\text{[Fe/H]}/\Delta R \)) and vertical (\( \Delta\text{[Fe/H]}/\Delta Z \)) metallicity gradient, as measured by \( \text{O} \), \( \text{B} \), \( \text{A} \) and early F-type stellar tracers observed in the LAMOST survey (sample I) along with a complementary sample from of giant stars observed within the third data release from the Gaia spacecraft (Gaia DR3, Gaia Collaboration et al. 2022a; Recio-Blanco et al. 2022) (sample II). In addition, we will also attempt to observationally constrain the level of any azimuthal variations that may lie on top of the metallicity gradient and discuss their implications. To facilitate the presentation of our results, this paper is outlined in the following way: in section 2 we outline the where the data for this project is sourced from, i.e. LAMOST (section 2.1) and Gaia (sections 2.2, 2.3) and the criteria used to ensure a high-quality sample. In section 3, we discuss the methods used to derive the metallicity gradients from the observable data. We present, in section 4, the primary results on the metallicity gradients in the Galactic disk with the tracer population and show that there is detectable azimuthal variation in the metallicity distribution at a given radial annulus. In section 4, we also interweave the discussion of our results in the context of what is currently known about the Galactic metallicity gradients along with the how the azimuthal variation might fit into the picture. With new data from the Gaia spacecraft now available, including the spatial positions and chemistry for millions of stars, in section 5, we take an initial look at the azimuthal variations in the metallicity structure in the disk with the Gaia DR3 data and discuss future prospects for chemical cartography with this exciting dataset. Finally, we summarize and conclude in section 6.

2 DATA

In this section, we describe the data required to carry out aims of this work, namely to explore the metallicity gradient and the azimuthal variation using hot stars from LAMOST and a complementary data set from Gaia DR3. More specifically, in section 2.1, we define the target selection and metallicities derived from LAMOST spectra for the sample. In section 2.1, we discuss the construction of the complementary sample using Gaia DR3. Finally, in section 2.3, we describe how we determine the spatial positions and velocities for our sample using data from Gaia DR3.

2.1 The Hot Stars in the LAMOST Survey

We begin our investigation with an existing catalogue, presented in Xiang et al. (2021), of ~332,000 massive (\( M \gtrsim 1.5 \text{ M}_\odot \), e.g., see their Figure 12), hot (\( T_{\text{eff}} > 7000 \text{ K} \)) stars identified in the LAMOST spectral dataset. The LAMOST survey (see more details at Cui et al. 2012; Zhao et al. 2012, and references therein) has collected low-resolution (\( R = \lambda/\Delta\lambda \sim 1800 \)) optical (\( 3800 < \lambda < 9000 \) Å) spectra for more than 8 million stars in the northern hemisphere (i.e., declinations larger than –10°). The spectra have been used to derive stellar atmospheric parameters (i.e., \( T_{\text{eff}} \), \( \log g \), [Fe/H], V sin i) and chemical abundances (for up to 16 elements) through both \( \chi^2 \) minimization with a grid of synthetic spectra (e.g., Xiang et al. 2015b) as well as through machine learning (e.g. Ting et al. 2019; Xiang et al. 2019, 2021). These pipelines have been employed upon mostly FGK-type stars and have enabled the exploration of metallicity gradient of the Milky Way. Only within the last year, novel machine learning algorithms have been deployed on the \( \sim 10^5 \) hot stars within LAMOST to derive their stellar parameters (Xiang et al. 2021). These newly derived stellar parameters for hot stars represents a large, powerful sample of
relatively young stars to not only explore the radial and vertical metallicity gradient but also any azimuthal variations in the metallicity distribution, which has been predicted in recent theoretical work (e.g., Di Matteo et al. 2013; Grand et al. 2016; Spitoni et al. 2019; Carr et al. 2022). Below we briefly describe the method for selecting and inferring stellar parameters for hot stars in the LAMOST survey.

In order to construct a catalogue of stellar atmospheric parameters, and most importantly metallicity, using LAMOST, Xiang et al. (2021) began by selecting a candidate list of hot stars. They did this by cross matching all stars that are both classified by the LAMOST DR5 and DR6 pipelines as O, B, A and early F-type with an all sky hot star catalogue outlined in Zari et al. (2021). The latter was based on Gaia DR2 photometric and astrometric data (Gaia Collaboration et al. 2018) along with complementary data from 2MASS (Cutri et al. 2003). After obtaining ~844,000 candidate hot stars, Xiang et al. (2021) derived the stellar atmospheric parameters (T$_{\text{eff}}$, log g, [Fe/H], Vsin i), which they refer to as stellar labels, using a modified version of The Payne (Ting et al. 2019). This ‘HotPayne’ tool uses a neural network algorithm, which models the fluxes in each spectrum as a non-parametric function of the stellar labels and was trained on a synthetic grid of spectra. For this, a Kurucz model spectral grid was constructed using SYNTH and convolved to the appropriate resolution with the known line spread function of the LAMOST spectra. A neural network was trained on the large synthetic grid, which enables efficient and precise spectral interpolation. This interpolation is then used to derive the stellar atmospheric parameter with the LAMOST spectrum. We refer the reader to Ting et al. (2019) and section 4 of Xiang et al. (2021) for a more detailed discussion of The Payne and how it was modified to work with the hot stars covered in this work. While the catalogue presents the atmospheric abundance of silicon (in addition the T$_{\text{eff}}$, log g, [Fe/H]), the authors note that these abundances likely have large systematics and as such we choose not to use these values.

With these data in hand, we are in a position to determine the radial and vertical metallicity gradient for relatively young hot stars in the Galactic disk. However, before we do that, we must ensure that both the spatial positions and the metallicities for the stars are precise enough to carry out this work. Therefore, we must apply some quality control cuts to the initial dataset to achieve a sample of stars where the spatial positions and metallicities are reasonable. We attempt to limit these cuts to the minimum number required to achieve a large sample while also ensuring precise spatial and chemical properties. There are two main sets of quality criteria cuts: those required to achieve high-quality metallicity from the LAMOST spectra (this section) and those required to achieve high-quality spatial positions (see section 2.3).

Following the recommendations by Xiang et al. (2021), we apply the following cuts on the LAMOST hot star catalogue:

(i) Remove stars with log g less than 2 dex or larger than 5 dex – Stars with log g below 2, which were identified in section 5.3 of Xiang et al. (2021) to potentially be chemically peculiar stars, likely have incorrectly determined surface gravities. Additionally, we remove stars with log g larger than 5 dex because these stars are either likely hot subdwarfs where the stellar atmospheric parameters will be poorly determined due to extrapolation.

(ii) Remove stars with Vsin i less than 0 – Negative Vsin i values were allowed by their pipeline as an extrapolation and would require a visual inspection of the spectra in order to determine whether it is an artifact or astrophysical.

(iii) Remove stars with T$_{\text{eff}}$ larger than 25 000 K – These extremely hot O-type stars will likely have significant non-local thermodynamic equilibrium (NLTE) corrections that could cause issues with the reported stellar parameters (e.g., see Figure 11 of Xiang et al. 2021).

(iv) Remove stars with a signal-to-noise ratio (SNR) below 30 – To achieve the high-quality estimates in the stellar atmospheric parameters, a SNR cut had to be applied.

(v) Remove stars with ‘chi2ratio’ value larger than 10 – As noted in section 5.2 of Xiang et al. (2021), the quality of the spectral fits were defined using a chi2ratio flag. This flag is derived by taking the deviations of the reduced $\chi^2$ from the median value at a given SNR and T$_{\text{eff}}$. By removing stars with a ‘chi2ratio’ value larger than 10, we are removing stars whose spectral fits have reduced $\chi^2$ values that are 10σ outliers compared to others at comparable T$_{\text{eff}}$ and SNR.

(vi) Stellar parameters and radial velocities (RVs) must be defined with reasonable uncertainties – We remove stars with unknown or large uncertainties ($\sigma$RV $> 100$ km s$^{-1}$) in RV. We do this because ultimately we will want to compute the spatial positions and velocities of our stars and without reasonably precise RVs we will be unable to do this. Further we require that T$_{\text{eff}}$, log g and [Fe/H] are all known. Since this study will focus on the metallicity gradient in the Galactic disk, it is critical that we have reasonable measured metallicities. As such we further require that star have a metallicity uncertainties, $\sigma$[Fe/H], less than 0.20 dex. We can change this criteria by more than a factor of 2 before seeing any changes in the results.

In Section 4.7 of Xiang et al. (2021), they compared their catalogue of stellar atmospheric parameters for hot OBA-type stars against the literature to quantify the level of systematics against other studies. Their results indicate that stars with T$_{\text{eff}} > 25,000$ K or log g < 2 dex, have systematics at the level of 3000 K and 0.80 dex, respectively. This is why we choose to cut stars in these parameter regimes. The authors show (see their Figures 10, 11, and 12) that with the above cuts, there are minimal systematic offsets between the literature (and as a function of SNR) in the atmospheric parameters. We note that while systematic effects are expected to be low, the catalogue employed here from Xiang et al. (2021), does not consider NLTE effects, a key limitation to their (and subsequently this) study.

Upon applying these initial cuts to achieve high-quality chemical properties, we were left with an initial sample of ~140 000 hot stars with T$_{\text{eff}} > 7000$ K. We must also consider quality cuts on the astrometric data required for the spatial positions and namely the derivation of R and Z (see section 2.3).

2.2 Complementary Sample: Gaia DR3 Gradient Sample

While the hot star sample from LAMOST allows us to probe a relatively young (<2 Gyr) tracer population, with the re-
lease of millions of metallicities all across the sky from Gaia DR3 (Gaia Collaboration et al. 2022a; Recio-Blanco et al. 2022), we are in a position to have a complementary sample of tracer stars that cover a wider range of azimuthal angles in the Galactic disk. With this complementary sample, we aim to only (1) validate that the methodology we use to derive the radial and vertical gradients give reasonable and consistent result with Gaia Collaboration et al. (2022b), and (2) explore the azimuthal variations for stars in the Galactic mid-plane (see section 5). We leave further investigations (e.g., exploring the radial and vertical gradients and azimuthal variations as a function of spectral type or age) with this dataset to future studies.

To construct a complementary Gaia sample, we follow the exact ADQL query from the ‘gradient sample’ from Gaia Collaboration et al. (2022b). This sample is defined in Section 2.5 of Gaia Collaboration et al. (2022b). More specifically, to obtain this complementary sample, we begin carrying out the ADQL query outlined in Listing 3 in Appendix B of Gaia Collaboration et al. (2022b). This sample was specifically constructed to optimize the quality of metallicities and spatial positions. To avoid potential selection biases, we choose to specifically focus here on a sample of bright giant stars (e.g., Gaia Collaboration et al. 2022b). More specifically, we require that the effective temperature ($T_{\text{eff}}$) measured from the Gaia spectra are less than 4700 K and that the surface gravity was less the log $g < 2.0$ dex. This is motivated by the desire to have a disk sample of stars that cover a large swath of the disk (hot OBA-type stars are poorly sampled in those stars with quality chemical measurements in Gaia DR3). With the initial gradient sample in hand from the Gaia Archive, we then cross-match that with the distance catalogue of Boeche et al. (2013b, 2014; ¨Onal Ta¸s et al. 2016; Yan et al. 2018; Gravity Collaboration et al. 2021). Uncertainties in metallicities in the gradient sample catalogue of giant stars is 0.04 dex. With a high-quality chemical sample from Gaia DR3, we must apply a set of quality cuts on the astrometric data required for the spatial positions and namely the derivation of $R$ and $Z$.

### 2.3 Galactic Positions and Kinematics with Gaia DR3

In order to obtain photometric and astrometric data for our sample we made use of data release 3 (DR3) from the Gaia spacecraft (Gaia Collaboration et al. 2022a). We cross matched the ~ 140 000 hot stars with quality stellar atmospheric parameters (see section 2.1 for more details) with Gaia DR3 using a 2° search radius. While stellar distances, required to determine the spatial position of each star, can be derived as the inverse of the parallax measured by Gaia DR3, parallax inversion can lead to significantly biased distances (e.g. Astraatmadja & Boailer-Jones 2016). Therefore, distances for each star were sourced from the catalogue outlined in Boailer-Jones et al. (2021). More specifically, we adopted the geometric distance estimates. This choice was motivated by the fact that we do not want to rely on color and magnitude information in the distance inference and as such it is recommended in section 5.3 of Boailer-Jones et al. (2021) to favor the geometric over photo-geometric distance estimates. In short, these distances are derived in a probabilistic Bayesian framework, whereby the posterior probability of a ‘true’ distance to each star given a measured parallax and its associated uncertainty is determined (see their Equation 1). The method adopted by these authors require a distance prior, a term which encodes the prior information that we have about the distances of stars in the Galaxy. The authors adopt a prior that is constructed from a model of the Milky Way (see their Equation 3 and their Figure 2 for more information on the distance prior). While, in principal, the prior affects the posterior distribution, in the limit where the uncertainties on the data (in this case the parallaxes reported from Gaia) are high-quality, the prior will not affect the posterior significantly.

For the purposes of this study, we want fairly precise spatial positions so that we can quantify the vertical and radial metallicity gradient. As such we limit ourself to stars which have parallax uncertainties better than 30% as well as remove stars with inferred distances from Boailer-Jones et al. (2021) with uncertainties larger than 30%. Together these cuts along with those outlined in section 2.1 reduces the initial LAMOST sample to ~135 000 stars. Additionally, this reduces the initial Gaia gradient complementary sample to ~840 000 giant stars. The median parallax uncertainty in both samples is around ~3%. With distances for each star, we compute the full 6 dimensional spatial position and velocity vectors for each star and its associated uncertainty. The spatial positions ($X$, $Y$, $Z$ location) and velocities ($U$, $V$, $W$) in a 3-dimensional Galactocentric-Cartesian frame were determined using Astropy’s SkyCoord class (Astropy Collaboration et al. 2013) with Gaia DR3 right ascension and declination, proper motions, with distances adopted from Boailer-Jones et al. (2021), and RVs adopted from LAMOST for the hot stars. RVs were adopted from Gaia DR3 for the complementary sample. We assume that the solar position is $(X, Y, Z) = (8.27, 0.00, 0.029)$ kpc and the Sun’s velocity in this reference frame is $(U, V, W) = (-12.9, 245, 7.78)$ km s$^{-1}$ (Drimmel & Poggio 2018; Gravity Collaboration et al. 2021). Uncertainties in the 6 dimension phase space ($X$, $Y$, $Z$, $U$, $V$, $W$) were determined by a Monte Carlo simulation with 1000 realizations, where each observational variable (i.e. right ascension and declination, proper motion, $RV$, and distance) were sampled from a random normal distribution.

We know from previous studies (e.g. Bilir et al. 2012; Boeche et al. 2013b, 2014; ¨Onal Ta¸s et al. 2016; Yan et al. 2019, and references therein) that metallicity gradients can and do depend upon whether one samples stars from the (kinematic) thin or thick disk. Therefore, we made use of the velocities derived above to probabilistically separate our stars into a (kinematic) thick and thin disk subpopulation. We computed the probability of a star belonging to the (kinematic) thin disk, thick disk, and stellar halo using the method outlined in Ramírez et al. (2013). With these probabilistic memberships, in both samples we remove probable halo stars (i.e., stars that have a 1% or higher chance of belonging to the stellar halo) since in this study we are fo-
Metallicity gradients in LAMOST and Gaia

Figure 1. Top: Two dimensional density diagram of the X-Y spatial positions of the hot OBAF star sample in LAMOST. For reference, the solar position is denoted as an orange star. The approximate location of the spiral arms in the Galaxy from Reid et al. (2014) are shown as thick black lines and their extend is marked by thick dashed lines. The color coding represents the number density of stars in log(N). Bottom: Two dimensional density diagram of the R-Z spatial positions of our full sample. The color coding represents the number density of stars in log(N).

Focussed on the Galactic disk. With this cut our final sample of 129 148 OBAF-type stars (and 847 214 complementary giant stars from Gaia DR3), which we will use to explore the radial and vertical metallicity gradient. The typical (median) uncertainties are 85 K, 0.10 dex, 0.08 dex in \( T_{\text{eff}} \), \( \log g \), and [Fe/H], respectively for the host star catalogue. The typical (median) uncertainties are 30 K, 0.10 dex, 0.04 dex in \( T_{\text{eff}} \), \( \log g \), and [Fe/H], respectively for the complementary Gaia DR3 sample. We note here that nearly all (>95%) of the sample is high probability (>90%) thin disk stars and as such with this particular sample is well suited for the exploration of the metal gradients in the thin disk.

In Figure 1, we show the X-Z (top) and R-Z (bottom) spatial distribution of the final sample of 129 148 OBAF-type stars. The color coding in each hexagonal bin represents the logarithm of the number of stars (log(N)) located in that bin. For reference, we also show the location of the Sun in both panels as an orange star as well as the approximate location of the spiral arms (taken from Reid et al. 2014, and shown as thick bold black lines surrounded by thick dashed lines). We can see that the sample covers Galactocentric radii between \( \sim 6.8 \)–12 kpc and have a vertical extent of \( |Z| \leq 2 \) kpc. In Figure 2, we make the same plot as in Figure 1, but instead of color coding by the log(N), each hexagonal bin is colored by the median metallicity. The top panel of Figure 2, shows that the inner Galaxy has, on average, a larger metallicity compare to the outer Galaxy (i.e., negative radial metallicity gradient). Additionally, the bottom panel of Figure 2, shows that the metallicity decreases as \( |Z| \) increases (i.e. a negative vertical metallicity gradient). In the following sections we will aim to quantify these qualitative trends.

3 METHODS: DERIVING THE METALLICITY GRADIENT AND AZIMUTHAL STRUCTURE

With the spatial and chemical information for 129 148 hot, massive stars spread out across the Galaxy, we are now in a position to derive the vertical and radial metallicity gradients. In addition, we will also constrain any azimuthal variations in the radial gradient. In this section, we will outline the methods used to derive the vertical and radial metallicity gradients and the azimuthal variations.

We choose to model both the radial and vertical metallicity gradients as linear functions with an intrinsic scatter. That is to say, that we model the radial metallicity profile...
of the Galaxy, as
\[ \text{[Fe/H]}|_R = \frac{\Delta\text{[Fe/H]}}{\Delta R} R + b_R \]  
(1)

In Equation 1, the metallicity at a particular Galactocentric radius (R) in the Galaxy, \[\text{[Fe/H]}|_R\], is linear function of the Galactocentric radius of a star (R) and the radial metallicity gradient, is denoted as \[\Delta\text{[Fe/H]}/\Delta R\]. Additionally, \(b_R\) represents the metallicity of the Galaxy at the Galactic center (i.e., \(R=0\)) if this metallicity gradient were valid across the full disk. While it is common in the literature to model the radial metallicity gradient as a simple linear function, it has been shown in young open cluster systems that the metallicity gradient is different in the outer disk compared to the inner disk with a break at Galactocentric radii of \(\sim 12-13\) kpc (e.g., Spina et al. 2022). Since our sample of OBAB stars from LAMOST have a median \(R = 9.3 \pm 1.15\) kpc, nearly all of our data is encompassed between \(6 < R < 12\) kpc. As such, we choose a single linear model rather than a broken piecewise linear function.

We choose to model the vertical metallicity gradients as linear function such that,
\[ \text{[Fe/H]}|_Z = \frac{\Delta\text{[Fe/H]}}{\Delta Z} Z + b_Z \]  
(2)

where in Equation 2, the metallicity at a particular absolute vertical height away from the Galactic plane, \[\text{[Fe/H]}|_Z\], is linear function of its absolute vertical height and the vertical metallicity gradient is denoted as \[\Delta\text{[Fe/H]}/\Delta Z\]. In this case, \(b_Z\) represents the metallicity of stars that are in the mid-plane of the Milky Way (i.e., with \(|Z| = 0\) kpc). In both cases, we will also fit an intrinsic scatter term \((\Lambda_R, \Lambda_Z)^2\), which represents the intrinsic dispersion around the radial and vertical metallicity gradient, respectively. We note that \(\Lambda_R\) and \(\Lambda_Z\) are actually \(2 \times 2\) tensors, which not only contain the dispersion around the line (denoted by \(\lambda^2\)) but also define the direction of the scatter (i.e., we assume that \(\Lambda_R = \frac{\lambda_R^2}{1+b_{\lambda m}} = \left( \frac{\Delta [\text{Fe/H}]/\Delta R}{\Delta [\text{Fe/H}]/\Delta R} - \frac{\Delta [\text{Fe/H}]/\Delta R}{\Delta R} \right) \)). This assumption is essentially that the scatter is perpendicular to the linear function with some variance (\(\lambda_R^2\)). Some limitations to this choice is that, we assume that the intrinsic scatter in the metallicity gradients are independent of location and that it is perpendicular to the linear relation between metallicity and radius (and height above/below the plane), which may not necessarily be true. We have also tried a model with intrinsic scatter that is only along the \([\text{Fe/H}]\) axis and found identical results in the gradients. Now that we have written down how we will model the data, we must choose a parameterization.

We want to model \(y_i\) as a linear function of \(\{x_i\}\) with some slope \(m\), intercept \(b\), and intrinsic scatter around this linear relationship \(\Lambda\). Under a Bayesian inference framework, we must start with with Bayes’ theorem, which states that:
\[ p(m, b, \Lambda | y, x, S_{\Lambda}) \propto p(y, x, S_{\Lambda} | m, b, \Lambda) p(m, b, \Lambda) \]  
(3)

where in Equation 3, \(p(m, b, \Lambda | y, x, S_{\Lambda})\) is the posterior probability distribution of the model parameters \((m, b, \Lambda)\) given the noisy measurements \((y, x, S_{\Lambda})\), \(p(y, x, S_{\Lambda} | m, b, \Lambda)\) is the likelihood of obtaining the noisy measurements given a defined model, and \(p(m, b, \Lambda)\) represents the prior information we have of the model parameters. In our case, the marginalized likelihood can be written down as:
\[ p(y, x, S_{\Lambda} | m, b, \Lambda) \propto \prod_{i=1}^N \frac{1}{\sqrt{2\pi \Sigma_{\Lambda}}} \exp \left( -\frac{\Delta y_i^2}{2\Sigma_{\Lambda}} \right) \]  
(4)

In Equation 4, we define a Gaussian likelihood function where \(\Delta y_i = y_i - (mx_i + b)\) and represents the difference between the measured and predicted value of \(y\) based on the linear model for the \(i\)th data point. Additionally, \(\Sigma_{\Lambda}^2 = v^T (S_{\Lambda} + \Lambda) v\), where here \(v^T\) equals the \(1 \times 2\) matrix \((-m 1)\). We encourage the reader to consult Hogg et al. (2010) and references therein for the detailed derivation of this marginalized likelihood probability distribution. In addition to the likelihood function, which is written in Equation 4, we also need to specify any prior information that we have about the model parameters, i.e., \(p(m, b, \Lambda)\). We choose relatively uninformative priors. Specifically, we select a uniform probability distribution in \(m\) between \(-2\) and \(2\) dex/kpc, a uniform prior in \(b\) between \(-2\) and \(2\) dex and a uniform prior in \(\lambda\) between 0 and 1 dex.

Ultimately, in Bayesian inference, we want to learn the full posterior distribution of the model parameters and how it depends on the observed data. To learn the model parameters and their uncertainties, we explore the multidimensional parameter space and find where the conditional probability of the model given the data is maximized. Since we do not know, a priori, the model parameters, we cannot solve this conditional probability. As such, maximizing the posterior probability requires maximizing the likelihood function multiplied by the prior (both of which we know). We use a Markov Chain Monte Carlo (MCMC) sampler set

\[ \lambda \]  

\footnote{In this pedagogical example, the noisy measurements, \(y_i\), and \(x_i\), could be thought of as the derived metallicity and Galactocentric radius (or absolute vertical height above the disk) to the \(i\)th star in our dataset, respectively. Therefore, \(S_{\Lambda}\) represents the covariance matrix that describes uncertainty in \([\text{Fe/H}]\) and \(R\) (or \(Z\)) and any covariances between them.}
metallicity gradients in LAMOST and Gaia

4 RESULTS AND DISCUSSION

4.1 Radial Metallicity Gradient

We begin by quantifying the radial metallicity gradient in the Galactic disk with the sample of 129 148 OBAF-type stars observed in the LAMOST survey. It is clear even in Figure 2, that the inner Galaxy (with $R < 8.3$ kpc) is more metal rich, on average compared to the outer Galaxy. It is also clear from that figure (as well as previous studies of the Galactic metallicity gradient, Önal Taş et al. 2016; Anders et al. 2017; Yan et al. 2019, and references therein), that the value of radial metallicity gradient is dependent on vertical extent of the sample. For this reason, we split our dataset into equally-sized vertical bins ranging from $0 < |Z| < 1.5$ kpc with a bin width of 0.2 kpc. We also require a minimum of 500 stars in each bin in order to adequately measure the radial metallicity gradient. For each bin in $|Z|$, we derive the parameters of the linear function ($m_R, b_R, \lambda_R$) defined in Equation 1 using the method outlined in section 3.

As an illustrative example of this fitting procedure, in Figure 3, we plot the [Fe/H] as a function of Galactocentric radius (R) for stars in our final hot star sample with $0.00 < |Z| < 0.20$ kpc. The [Fe/H] and R for these stars (background grey density), along with their respective uncertainties, are then input into our Bayesian inference (described in section 3). The solid thick red band in Figure 3 is the best fit linear model determined using Bayesian inference linear regression. Also shown are thin red lines (which make a red band due to highly constrained model) of 100 randomly selected linear models realizations from the Bayesian MCMC sampling. The derived metallicity gradient for these stars is $\Delta[\text{Fe/H}]/\Delta R = -0.078 \pm 0.001$ dex/kpc.

| $|Z|$ (kpc) | $\Delta[\text{Fe/H}]/\Delta R$ (dex/kpc) | $\sigma_{\Delta[\text{Fe/H}]/\Delta R}$ (dex/kpc) | $b_R$ (dex) | $\sigma_{b_R}$ (dex) | $\lambda_R$ (dex) | $\sigma_{\lambda_R}$ (dex) | N (dex) |

NOTE: Column 1 is center of the vertical $|Z|$ bin. The derived radial metallicity gradient slope and its uncertainty can be found in columns 2 and 3, respectively. The intercept of the linear model and its uncertainty are tabulated in columns 4 and 5, respectively. The intrinsic scatter around the linear radial metallicity gradient relation and its uncertainty can be found in columns 6 and 7, respectively.
where the number of stars in the bin is larger than 500. For reference, we also plot the $\Delta[Fe/H]/\Delta R$ from a representative (but very incomplete) set of previous studies from different surveys with a variety of tracers (Cheng et al. 2012; Boeche et al. 2013a; Hayden et al. 2014; Huang et al. 2015, grey diamonds/line), LAMOST survey FGK-type stars (Yan et al. 2019, brown circles/line), RAVE survey FGK dwarf stars (Boeche et al. 2013a, cyan circles/line), Gaia-ESO survey FGK-type stars (Bergemann et al. 2014, magenta stars), APOGEE red giant branch stars (Hayden et al. 2014, blue circles/line), and FGK dwarfs and giants from the Gaia DR3 survey (Gaia Collaboration et al. 2022b, magenta squares/line). The Galactic radial metallicity gradient becomes shallower (i.e., $\Delta[Fe/H]/\Delta R$ becomes less negative and closer to zero) with increasing height above the mid-plane. The radial metallicity measured using LAMOST OBAF-type stars (black line) is also consistent with other tracers (colored lines).

Figure 4. The metallicity gradient, $\Delta[Fe/H]/\Delta R$, as a function of absolute vertical height $(|Z|)$ away the Galactic mid-plane for for OBAF-type stars (black circles/line) used in this study. For comparison, we also show the radial metallicity gradient measured using: main sequence turn off stars in SEUGE (Cheng et al. 2012, red triangles/line), LAMOST survey red clump type stars (Huang et al. 2015, grey diamonds/line), LAMOST survey FGK-type stars (Yan et al. 2019, brown circles/line), RAVE survey FGK dwarf stars (Boeche et al. 2013a, cyan circles/line), Gaia-ESO survey FGK-type stars (Bergemann et al. 2014, magenta star), APOGEE red giant branch stars (Hayden et al. 2014, blue circles/line), and FGK dwarfs and giants from the Gaia DR3 survey (Gaia Collaboration et al. 2022b, magenta squares/line).

4.2 Azimuthal Variations

In addition to deriving the radial metallicity gradient (see section 4.1), in this study we are also interested in whether there are azimuthal variations in the metallicity distribution (or radial gradient). Such azimuthal variations in the metallicity gradient (and thus the metallicity distribution across the disk) have been predicted in simulations (e.g. Di Matteo et al. 2013; Grand et al. 2016; Khoperskov et al. 2018; Fragkoudi et al. 2018; Spitoni et al. 2019; Wheeler et al. 2021; Carr et al. 2022). Additionally, Hwang et al. (2019), uncovered azimuthal variations in the metallicity distribution of external galaxies observed in the MANGA survey (e.g., see their Figure 13). Interestingly, azimuthal variation were detected in close pair systems where a host galaxy had a companion nearby. While, small azimuthal variations (at the 0.02 dex level) have been detected in the Milky Way disk on relatively local samples of stars (e.g. Bovy et al. 2014; Antoja et al. 2017), in this work we expand to well beyond the solar neighborhood and use a different tracer population.
To quantify whether there are azimuthal variations, in Figure 5 we show the median metallicity as a function of X-Y position for stars with |Z| < 0.3 kpc (left panel). In addition, we also show the best-fitting model (using the procedure outlined in section 3) of the expected metallicity in the same X-Y space (middle panel). The residual between the observed metallicity at a given X-Y cell and the predicted metallicity in that same cell based on the radial metallicity relation is shown in the right panel. For reference, in all panels we show the location of the spiral arms as identified using high-mass star-forming regions (shown as black lines, Reid et al. 2014). In the right panel, we also show the location of the spiral arms, as determined by the order of the upper main sequence stars in Gaia (shown as black contours Poggio et al. 2021). Critically, if the same linear radial gradient model were a good fit to the data at a given radius, is defined as the observed metallicity subtracted from the predicted metallicity in that same cell based on the radial metallicity relation (e.g., little to no azimuthal metallicity structure), the residuals should be close to zero for the full X-Y extent of the data (and along azimuthal angles).

The right panel of Figure 5 illustrates that we find deviations upwards of 0.20 dex (at the ~2–3σ level) between the predicted and observed metallicity at a given X-Y position in the Galactic disk. Additionally, the residual level (indicated by the color bar in the right panel of Figure 5) appears to be dependent on where in the Galactic disk the stars are located. For example, we find that the observed metallicities at around X ~ ~8.6 kpc and Y ~ 1.5 kpc are higher than what is predicted from a our simple linear radial metallicity model. We also find that the observed metallicities at X ~ ~10.5 kpc and Y ~ ~1.5 kpc are, on average, lower than what is predicted from our linear model. We also see hints that the azimuthal variations are largest in the outer rather than inner Galaxy (in the range probed by this study), though a larger dataset that encompasses a wider swath of the Galaxy is required. Interestingly, for this OBAB-type sample of stars from LAMOST, we find that the azimuthal variations do not follow the expected location of the spiral arms (unlike for Poggio et al. 2022, and see section 5).

Figure 5. Left: The X-Y projection for the ~97 000 stars with 0.00 < |Z| < 0.30 kpc color-coded by the median metallicity derived with the LAMOST spectra. Middle: The X-Y projection of the metallicity gradient defined by the best fitting model. Right: The X-Y projection of the residual (color bar) between the observed metallicity (right panel) and the predicted metallicity (middle panel). For reference, in all panels the position of the spiral arms (as determined by high mass star forming regions) from Reid et al. (2014) are shown as black lines (both dashed and solid). In the right panel, we also show the position of the spiral arms (black contour), as determined by the upper main sequence from (Poggio et al. 2021). The residual, Δ[Fe/H], is defined as the observed metallicity subtracted from the predicted metallicity of each star given its Galactocentric radius. We find that there is structure at the 0.05–0.20 dex level. These residuals can be as large as 3 times the typical uncertainties in [Fe/H].
Figure 6. The average metallicity deviation at fixed radius, $<\delta[\text{Fe/H}]>$, as a function of azimuthal angle ($\phi$ in radians) for stars in the outer ($9 < R < 11$ kpc; black line) and in inner ($7 < R < 9$ kpc; blue line) Galactic disk. If all stars at a constant radius (regardless of azimuthal angle) had the same metallicity $<\delta[\text{Fe/H}]>$ would be zero. We find average metallicity deviation at fixed radius as high as $\sim 0.10$ dex, with slightly larger variations the outer disk (black line).

future work, we will compare more directly to simulations but the small azimuthal coverage makes those comparisons currently difficult.

4.3 Vertical Metallicity Gradient

In addition to deriving the radial metallicity gradient and the azimuthal variations in the metallicity distribution, we also use the LAMOST OBAF-type stars to explore the vertical metallicity gradient. We apply the same procedure, outlined in section 3, to derive both the radial and vertical metallicity gradients. Previous studies (e.g. Önal Taş et al. 2016, and references therein) have shown that the vertical metallicity gradient likely varies as a function of Galactocentric radius. Therefore, we split the stars into equally-spaced radial bins with $\sim 1$ kpc in size. In order to ensure that we can adequately derive the vertical metallicity gradient we also require a minimum of 500 stars per bin. In Figure 7 we show the vertical metallicity gradient derived using the OBAF-type stars observed in LAMOST (black circles). We also tabulate the full linear model fit parameters for each radial bin in Table 2.

We find that the vertical metallicity gradient changes with Galactocentric radius. In the solar neighborhood ($7 < R < 9$ kpc) the vertical metallicity gradient ranges between $-0.22 < \Delta[\text{Fe/H}]/\Delta Z < -0.15$ dex/kpc. The vertical gradient then becomes significantly shallower ($-0.05$ dex/kpc) towards the outer Galaxy. As illustrated in Figure 7, these values for the vertical gradient are largely consistent with other tracers, especially in the solar neighborhood. While there are some differences in our measured vertical metallicity gradient compared to others, the overall shallowing of the vertical gradient is seen in nearly all tracers. If more metal-poor thin disk stars are on average older than those which are metal-rich, the negative vertical metallicity gradient would imply that older thin disk stars can be found at larger vertical heights on average. This negative vertical metallicity gradient is therefore expected due to kinematic heating of thin disk population or early star formation in a more vertically extended disk.

5 EXPLORING THE AZIMUTHAL STRUCTURE IN METALLICITY DISTRIBUTION IN THE GALACTIC DISK WITH GAIA DR3

With the radial and vertical metallicity gradients measured and the azimuthal variations quantified for the LAMOST hot star sample (section 4), here we briefly discuss the future prospects of constraining azimuthal structure in the chemical maps of the Galactic disk using Gaia DR3. We are motivated to explore the use of Gaia DR3 data because it is all sky and encompasses a larger swath of azimuthal angles than the LAMOST dataset. In this section, we aim to simply explore whether the azimuthal variations can also be found in the the Gaia DR3 Gradient sample (outlined in section 2.2). Initially we used this dataset in section 3, to validate our method to derive the radial and vertical metallicity gradients. Using our method, we find that the radial
Metallicity gradients in LAMOST and Gaia

Table 2. Vertical Metallicity Gradient Fit Parameters across All Radial Bins

| R (kpc) | \(\Delta [\text{Fe/H}] / \Delta Z\) (dex/kpc) | \(\sigma \Delta [\text{Fe/H}] / \Delta Z\) (dex/kpc) | \(b_Z\) (dex) | \(\sigma b_Z\) (dex) | \(\lambda_Z\) (dex) | \(\sigma \lambda_Z\) (dex) | N |
|---------|----------------------------------|----------------------------------|--------------|-----------------|-----------------|-------------------|---|

| 12.5    | -0.040                           | 0.022                            | -0.506       | 0.014           | 0.418           | 0.006             | 3213  |
| 13.5    | -0.066                           | 0.066                            | -0.492       | 0.043           | 0.515           | 0.017             | 525   |

NOTE: Column 1 tabulates the center of the radial bin (in kpc). The derived vertical metallicity gradient slope and its uncertainty can be found in columns 2 and 3, respectively. The intercept of the linear model and its uncertainty are tabulated in columns 4 and 5, respectively. The intrinsic scatter around the linear \([\text{Fe/H}]\)-\(Z\) relation and its uncertainty can be found in columns 6 and 7, respectively.

Figure 8. Left: The X-Y projection for the \(\sim 480,000\) stars in the complementary Gaia DR3 gradient sample of giant stars with \(0.00 < |Z| < 0.30\) kpc color-coded by the median metallicity derived with using the Gaia RVS spectra. Middle: The X-Y projection of the metallicity gradient defined by the best fitting model. Right: The X-Y projection of the residual (color coding) between the observed metallicity (right panel) and the predicted metallicity (middle panel). Similar to Figure 5, in all panels the position of the spiral arms (as determined by high mass star forming regions) from Reid et al. (2014) are shown as black lines (both dashed and solid). In the right panel, we also show the position of the spiral arms (black contour), as determined by the upper main sequence, from Poggio et al. (2021). Interestingly, the residuals (right panel) show azimuthal variations that track with the location of the spiral arms of (shown as black contours Poggio et al. 2021).

The gradient is consistent with those reported in Gaia Collaboration et al. (2022b). This effectively validates that our method give reasonable results for the radial and vertical gradients.

However, with these data, we can also constrain whether there is azimuthal structure using the same procedures as the LAMOST dataset (see section 4.2). We start by taking a subsample of \(\sim 480,000\) stars in the complementary Gaia gradient sample of giant stars with \(0.00 < |Z| < 0.30\) kpc and deriving the radial metallicity gradient. In the left panel of Figure 8, we show the X-Y projection of the metallicity distribution in the Galactic disk for these \(\sim 480,000\) giant stars, which are \(0.30\) kpc from the mid-plane of the Galactic disk. The middle panel of Figure 8 represents the best fitting radial metallicity gradient (i.e., the expected \([\text{Fe/H}]\) at a given metallicity based on the data). In the right panel of Figure 8, we show the residuals between the observed and predicted metallicities (i.e., the observed metallicity subtracted from the predicted metallicity of each star given its Galactocentric radius). For reference, in all panels we show the location of the spiral arms as identified using high-mass star-forming regions (shown as black lines, Reid et al. 2014). We also show in right panel of Figure 8, the location of the spiral arms, as determined by the over density of the upper main sequence stars (shown as black contours Poggio et al. 2021). Remarkably, we find (1) there is azimuthal structure in the residuals and it is at nearly the same levels (\(\sim 0.10\) dex) as the LAMOST sample, and (2) the residuals show azimuthal structure that seems to be close to the expected location of the spiral arms (e.g., Poggio et al. 2021). This result indicates that giant stars near the spiral arms (as traced by the upper main sequence) may contain slightly more metals than those which lie in between the arms. This is also consistent with Poggio et al. (2022) who find metal-enhanced elongated structures located in near the spiral arms in the Galactic disc with a slightly different giant subsample of the Gaia DR3 data. We note that the location of the spirals as traced by high mass star formation regions (e.g. Reid et al. 2014), is slightly different than those traced by the upper main sequence (similar to the result from Poggio et al. 2021). This result carries the same limitations as the OBA sample above, namely that the abundances derived in Gaia are computed assuming a range of assumptions (e.g., local thermodynamic equilibrium), and the methodology outlined above (in Section 3), explicitly models the data under a Bayesian formalisms assuming an intrinsic dispersion around the metallicity gradient independent of location. Further interpretation of these results will require chemo-dynamical modeling (e.g. Di Matteo et al. 2013; Khoperskov et al. 2018; Fragkoudi et al. 2018; Carr et al. 2022). We stress that this is just a first exploration of the azimuthal variations in metallicity in Gaia data and that followup work will be required to fully understand and map these large-scale chemical structures in the Galactic disk.
6 SUMMARY

The industrial revolution in astrometric and spectroscopic surveys of the Milky Way has enabled a large-scale mapping of its disk. In particular these new large-scale datasets have allowed us to chemically map our Galaxy, leading to a refinement of our understanding of the way the Galaxy is structured. In particular, these data have been routinely used to show that our Galaxy has negative radial and vertical metallicity gradients. However, the presence (or lack thereof) and size of azimuthal variations in the metallicity distribution of stars observed in our Galactic disk has been not well explored despite numerous theoretical studies. Therefore, in this work we aim to use a sample of relatively hot and young stars from the LAMOST survey along with a complementary sample of metallicities from the Gaia DR3 radial velocity spectrometer (see section 2) to constrain: (1) the radial gradient in the Galactic disk, (2) the vertical gradient in the Galactic disk, and (3) the level of any azimuthal variations that may lie on top of the metallicity gradient and how it depends on azimuthal angle. The latter of these will determine whether azimuthal variations in the metallicity distribution follow the spiral pattern in the Milky Way. In order to do this, we set up a Bayesian framework (see section 3) to derive the linear radial and vertical metallicity gradient, which accounts for the uncertainties in [Fe/H], R, and Z.

Our main results (see sections 4, 5) can be summarized as follows:

(i) We find a negative radial metallicity gradient, ∆[Fe/H]/∆R, which can be as steep as −0.078 ± 0.001 dex/kpc for OBAB-type stars in the Galactic disk observed in the LAMOST survey. This gradient is broadly consistent with previous studies of the metallicity gradient with different tracers and surveys. This result is broadly consistent with other tracer and studies. This is consistent with with other trace and studies.

(ii) The radial metallicity gradient is steepest in the Galactic mid-plane (with ∆[Fe/H]/∆R = −0.078 ± 0.001 dex/kpc) but becomes shallower (and nearly flat) as one goes to a larger vertical extent (∆[Fe/H]/∆R decreases to −0.001 ± 0.004 dex/kpc at 1.3 kpc above the mid-plane). This is consistent with other tracer and studies.

(iii) We find that there is resolvable azimuthal structure in deviations away from the radial metallicity gradient. These deviations can be as large as 0.05–0.10 dex. Excitingly, these azimuthal variations show large scale structure and are predicted to originate due to secular processes (e.g. Di Matteo et al. 2013; Khoperskov et al. 2018; Fragkoudi et al. 2018; Wheeler et al. 2021) as well as tidal effects from the passage of the Sagittarius dwarf (e.g. Carr et al. 2022). The extent of azimuthal angles probed in this study is somewhat limited, preventing direct comparisons with the simulation. Interestingly, while the azimuthal variations in the LAMOST OBAF star sample do not track the expected location of the spiral arms (see Figure 5), the complementary Gaia DR3 sample of giants show azimuthal variations in the metallicity distribution that grossly follows the spiral arms (see Figure 8). This suggests that while chemical cartography can reveal the spiral structure of the Milky Way (e.g., see also Poggio et al. 2022), it is dependent on tracer population. Regardless, the presence and size of the azimuthal variations is irrespective of which sample is used. Further exploration on the azimuthal structures will be done in followup studies.

(iv) We find a negative vertical metallicity gradient, ∆[Fe/H]/∆Z, which can be as steep as −0.22 ± 0.01 dex/kpc for OBAB-type stars in the Galactic disk observed in the LAMOST survey. This gradient is broadly consistent with previous studies of the metallicity gradient with different tracers.

(v) The vertical metallicity gradient in the solar neighborhood (7 < R < 9 kpc) ranges between −0.22 < ∆[Fe/H]/∆Z < −0.15 dex/kpc. The vertical metallicity gradient becomes shallower in the outer galaxy (12.5 < R < 13.5 kpc) ranging between −0.06 < ∆[Fe/H]/∆Z < −0.04 dex/kpc. This is consistent with other tracer and studies. This result is broadly consistent with other tracers, and surveys.

Taken together, our results show that while vertical and radial metallicity gradient are present in the Milky Way, there are further (azimuthal) complexities buried in the data that must be explored (see section 5). We recommend further exploration in the azimuthal structure be carried out controlling for tracer population (i.e., spectral type) and stellar age. The results presented here illustrate the power in chemical cartography in this new industrial era of Galactic and stellar astronomy.

DATA AVAILABILITY

The data (Gaia DR3 and the hot star sample from the LAMOST survey) underlying this article were accessed from both the Gaia Archive (https://gea.esac.esa.int/archive/), and the Strasbourg astronomical Data Center (CDS) (https://cdsarc.cds.unistra.fr/viz-bin/cat/J/A+A/662/466). The derived data generated in this research will be shared on reasonable request to the corresponding author.

ACKNOWLEDGEMENTS

KH thanks the anonymous referee for both thorough and helpful comments that improved the manuscript! KH also thanks Carrie Filion, Chris Carr, Paula Jofré, Kathryn Johnston, Adrian Price-Whelan, Dan Foreman-Mackey, Zack Maas, Catherine Manea, Zoe Hackshaw, and Maddie Lucey for fruitful discussions that helped improve this work. KH acknowledges support from the National Science Foundation grant AST-1907417 and AST-2108736 and from the Wotton Center for Astrophysical Plasma Properties funded under the United States Department of Energy collaborative agreement DE-NA0003843. This work was performed in part at Aspen Center for Physics, which is supported by National Science Foundation grant PHY-1607611. This work was performed in part at the Simons Foundation Flatiron Institute’s Center for Computational Astrophysics during KH’s tenure as an IDEA Fellow. This project was developed in part at the Gaia Hike, a workshop hosted by the University of British Columbia and the Canadian Institute for Theoretical Astrophysics in 2022 June.

The following software and programming languages made

MNRA 000, 1–14 (2022)
this research possible: topcat (version 4.4; Taylor 2005); Python (version 3.7) and accompany packages astropy (version 2.0; Astropy Collaboration et al. 2013), scipy (Virtanen et al. 2020), matplotlib (Hunter 2007), NumPy (van der Walt et al. 2011), and emcee (Foreman-Mackey et al. 2013). This research has made use of the VizieR catalog access tool, CDS, Strasbourg, France. The original description of the VizieR service was published in A&AS 143, 23.

This work has made use of data from the European Space Agency (ESA) mission Gaia (https://www.cosmos.esa.int/gaia), processed by the Gaia Data Processing and Analysis Consortium (DPAC, https://www.cosmos.esa.int/web/gaia/dpac/consortium). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the Gaia Multilateral Agreement.

This work has made use of data products from the Guoshoujing Telescope (the LAMOST). LAMOST is a National Major Scientific Project built by the Chinese Academy of Sciences. Funding for the project has been provided by the National Development and Reform Commission. LAMOST is operated and managed by the National Astronomical Observatories, Chinese Academy of Sciences.
