Abstract
In this work, cedar cone (CC), an abundant agricultural waste in north Algeria, was used as an adsorbent in batch mode for elimination of cationic dye crystal violet (CV) from aqueous solution. The functional groups were determined by Fourier transform infrared spectroscopy. The adsorption process was examined as the functions of adsorbent dose, contact time, initial CV concentration and solution pH. The isotherms adsorption were studied at different temperatures (289–318) K, the shape obtained was compatible with the “L-type” isotherm. The equilibrium data were fitted by Langmuir and Freundlich models, using non-linear regression method. The results show that equilibrium data were best fitted by Freundlich model, with good coefficient of correlation ($R^2 = 0.991$). The adsorption processes could be described by the pseudo-second order kinetic model with $R^2 \geq 0.997$. The results proved that CC could be a potential abundant adsorbent for the removal of CV from aqueous solution.

1 Introduction
We live in a world where everything is colourful including our clothes, foods, cosmetics and pharmaceutical drugs, etc. [1]. The production of synthetic dyes is increasing, because of ease of synthesis, speed of production and the wide variety of colours available compared to natural dyes [1]. Shukat et al. [2] have mentioned that more than 100,000 dyes, are synthesized with 700,000 metric tons production annually.

Synthetic dyes have a diversified chemical structure, that stems from the diversity of the chromophore groups that compose them (azo groups, anthraquinone, triaryl-methane and phthalocyanine) and the diversity of application techniques (reactive, direct, dispersed and vat coloration) [1].

Due to their complex chemical structure, some of these dyes are stable to light and oxidizing agents, possess a high resistance to biodegradation and persist a long time in the environment [3, 4].

During the colouring process, dyes are absorbed by the product; a certain amount will end-up in the wastewater. This can cause serious environmental problems [5]. The release in the environment of synthetic dyes by various industries, mainly the textile industry, can contaminate the receiving environment. Since, these compounds are generally carcinogenic or toxic for humans. Even a low concentration, these colouring agents are highly visible and can be toxic to the aquatic environment [3, 6]. In addition, even if the colouring molecules themselves are not necessarily originally toxic, their derivatives from biodegradation processes may become toxic [1].

Among many classes of synthetic dyes, triphenyl-methane class of dyes is most versatile due to their diverse applications [2]. Crystal violet (CV) dye is a synthetic cationic dye and transmits violet colour in aqueous solution [7]. It is also known as Gentian Violet, Basic
Violet 3 and methyl violet 10B, from Rosanilines group, which is part of the Triphenylmethanes. It is a mixture of 5 and 6-methyl hydrochloride hydrides. (Penta methyl para rosaniline and hexamethyl violet), It is soluble in water, and in alcohol [2, 5, 8]. Crystal violet is used in textile industry, paint and printing ink industry. In the medical community, it is used as a biological stain and is the active ingredient in Gram's stain. In animal husbandry and veterinary medicine, it is employed as a bacteriostatic agent veterinary and poultry feed, as well as biotechnology biological studies etc [2, 9].

CV is toxic, mutagenic, carcinogenic and poisonous to mitotic division process. It can be absorbed through the skin, causing irritation; it is harmful by inhalation and ingestion. In extreme cases, it has been reported severe kidney failure in repose to exposure to CV. It is highly toxic to mammalian cells; it is also non-biodegradable and persists in the environment for longer time. It is therefore very important to remove this dye from water and wastewater [2, 10].

Different techniques of treatment have been used to remove pollution by dyes from release, whether physicochemical, chemical or biological treatments such as flocculation-coagulation, precipitation, adsorption, membrane filtration, electrochemical techniques and ozonation. Advanced oxidation processes (AOP) are among the recent techniques that have been used for the oxidation of compounds difficult to degrade by traditional physicochemical and biological methods [11]. However, the AOPs rely on the uses of strong oxidant such as the OH* radical, produced by different reactions and based on the use of more or less expensive chemical reagents. The orientation towards a less expensive treatment technique such as adsorption has been an attractive solution. Adsorption is a simple design technique and less expensive compared to other treatment techniques, especially if the adsorbent is a natural waste available in nature in abundance. This technique has shown great efficiency in the purification of waters contaminated by dyes even at high concentrations [12].

Various studies have focused on the use of inexpensive materials that are readily available for use as adsorbents, for elimination of CV dye from aqueous solution. For examples, Rice husk [9], pyrophyllite [13], Mangrove plant (Sonneratia apetala) leaf powder (MPLP), Mangrove plant (Sonneratia apetala) fruit powder (MPFP), Mango (Mangifera indica) leaf powder (MLP), Tamarind (Tamarindus indica) fruit shell powder (TFSP), Teak tree (Tectona grandis) bark powder (TTBP), Almond tree (Terminalia catappa) bark powder (ATBP) [14]. Potato peels [15], clay [16], Kaolin [17], Mango stone biocomposite [2] and coffee husks [18] showed promising efficiencies for CV adsorption.

Therefore, the aims of this work, is to explore the aptitude of an abundant low-cost naturel adsorbent, cedar cone (CC), for elimination of crystal violet (CV) from aqueous solutions. The use of alternative of activated carbon, which is very expensive. In this study, the effects of adsorbent such as sorbent dosage, contact time, initial dye concentration and solution pH were evaluated. Isotherms adsorption were constructed at different temperatures (298–328 K) and the equilibrium data were fitted by the Langmuir and Freundlich model.

## 2 Materials and method

### 2.1 Adsorbate

Crystal violet, structure given in Fig. 1, was purchased from RAL Diagnostics; it was used without further purification. A stock solution of the dye containing 0.5 g/L was prepared by dissolving the required amount of dye in distilled water. Solution for adsorption experiments study were prepared from the stock solution by appropriate dilution.

The dye concentration was measured in the UV spectrophotometer at the wavelength of 590.5 nm, the spectrum absorption of CV is shown in Fig. 2. The aqueous solution of CV had a pH of 5.55, and for the study of pH effect, the solution dye pH was adjusted by using hydrochloric acid or sodium hydroxide solution at 0.1 mol/L. The important properties of the CV are summarized in Table 1.

### 2.2 Adsorbent

Cedar is a genus of conifer of the Pinaceae family, native to the Middle East, North Africa and Himalayas, including majestic species of trees 25–50 m tall. Female cedar

![Fig. 1 Chemical structure of CV](image)
cones (CC) are oblong ovoid, 6–11 cm in long and 4–6 cm in diameter, they are erect towards the sky and thin scales are detached before the fall of the cone; the triangular seeds are winged. Cedar cones (Fig. 3) is available in large quantities in northern Algeria. It was collected from the Chelia forest in Khenchla, Algeria. Cedar cones were sun dried for 5 days to reduce the moisture, crushed and sieved to obtain an average particle size between 1 and 1.25 mm. After that, the crushed cedar cones were extensively washed with distilled water until complete elimination of color and impurities. Then, it were dried in an oven (Mamert, Allemagne) at a temperature of 378 K until constant weight.

2.3 Batch adsorption study

The adsorption experiments of CV by CC were carried out in a batch reactor perfectly agitated and thermostated, the batch system consist to mix a fixed adsorbent mass with 100 mL of aqueous dye solution at concentration of 50 mg/L. The mixture was stirring by stirrer (IKA Heidolph, EUROSTAR digital, France) at 300 rpm in thermostatic water bath (KOTTERMANN, France) at 298 K until equilibrium is reached. At appropriate time intervals, 3 ml of mixture solution was withdrawn and centrifuged (sigma 1-6P, France) at 3000 rpm for 5 min and the dye remaining

Fig. 2 Absorption spectrum of CV

Fig. 3 Different states of cedar cones
unadsorbed in the supernatant liquid was determined using spectrophotometer (SHIMADZUUV-1601, Germany). To study the effect of adsorbent dose, various mass of cedar cone (0.2–4 g) was adding into a series of backer’s flasks, each containing 100 mL of crystal violet dye solution with initial concentration of 50 mg/L. The adsorption isotherm study was conducted at three different temperatures (298, 308 and 318 K) for the dye concentration (10–200 mg/L). The amount of dye adsorbed per unit mass of the adsorbent is calculated from the residual concentration in solution according to the following equation:

$$q_t = \frac{C_0 - C_f}{m} \times V$$

(1)

where $q_t$: amount of pollutant per unit mass at t time (mg/L); $C_0$: initial concentration (mg/L); $C_f$: residual concentration at time (mg/L); $V$: volume of solution (L); $m$: mass of the adsorbent (g).

The percent removal of dye $E$ (%) is computed from the following expression:

$$E(\%) = \frac{C_0 - C_f}{C_0} \times 100$$

(2)

3 Results and discussion

3.1 The FTIR analysis of cedar cone

In order to identify the functional groups present on the surface of cedar cone surface, we have analysis the adsorbent by Fourier transforms infrared (FTIR) spectroscopy (Agilent technology Cary 600 FTIR spectrometer), the FTIR spectral range is from 400 to 4000 cm$^{-1}$.

The FTIR spectrum (Fig. 4) shown many bands; reflecting the complex nature of the adsorbent. The bands at about 464.8 cm$^{-1}$ can be assigned to the stretching of C–C, the pics at 1028.0 cm$^{-1}$ can be attributed to the C–O–C elongation. The bonds observed at 1382.9 cm$^{-1}$ could be assigned to asymmetric band of CH$_3$ or C–(CH$_3$)$_2$ [20], since the pic observed at 1514.0 cm$^{-1}$ is attributed to the deformation of N–H to nitro aromatic compound. The bands observed at 1627.8 cm$^{-1}$, 2366.5 cm$^{-1}$, 2856.4 cm$^{-1}$ can be assigned to the elongation of C=C, –C≡N–, –C≡N– respectively. The bands between 2856.4 and 2923.9 cm$^{-1}$ could be assigned to the aliphatic C–H groups. Two other pics have been observed at 3417.6 cm$^{-1}$ and 3759.0 cm$^{-1}$, indicates the presence of OH group which can be attributed to the water adsorbed on the CC surface [21, 22].

3.2 Effect of sorbent dose and contact time

To investigate the influence of adsorbent mass on dye adsorption, experiments were conducted at an initial CV concentration of 50 mg/L, while the adsorbent mass was varied from 0.2 to 4 g and the other parameters are kept constant. Figure 5 shows the effect of the adsorbent dose on the percent removal of CV. It has been observed that the percent removal of CV depends on the dose of cedar cone. It increased rapidly with increasing CC dose up to 1 g, and then remained almost unchanged between 1 and 4 g from 96.12 to 97.35% (Fig. 5). The highest percentage of elimination observed is 99.62%, almost a total elimination for a dose of 2.5 g. This mass was chosen as the optimal mass. The increase in the percent removal of CV is explained by the increase of the available adsorption surface sites.

The effect of contact time on CV removal by CC showed more or less rapid adsorption of the dye during the first 90 min as the adsorbent dose increased from 0.2
to 1 g. The equilibrium time decrease from 30 min until reach 5 min when the dose of adsorbent passed from 1 to 4 g. A faster equilibrium time, indicate a high degree of affinity between the dye and the adsorbent.

### 3.3 Effect of initial dye concentration

The effect of initial dye concentration on CV adsorption by CCs was studied by varying the initial concentration as follows 10, 25, 50, 75, 100, 175 and 200 mg/L. Figure 6 illustrates the adsorption of CV for different initial concentrations of dye at 298 K as function of contact time. Figure 6 show that the amount adsorbed increased with the increase in the concentration of dye. When the initial CV concentration was increased from 50 to 200 mg/L, the adsorption uptake of CC increased from 0.39 to 7.7 mg/g. The increase in the initial dye concentration causes an increase in the driving force, which leads to the weakness of all the resistances of the dye between the aqueous and solid phases, which results in an increase of adsorption [23].

### 3.4 Effect of solution pH

To study the effect of solution pH on the adsorption of CV, the pH was adjusted by adding NaOH or HCl at 0.1 mol/L. The effect of pH solution was study at the optimum adsorbent masse (2.5 g) and at stirring speed of 300 rpm with 50 mg/L initial concentration of dye. The pH was varied from 2 to 12, the result obtained is shown in Fig. 7. The result shown that at low pH (strong acidic pH), the amount of dye adsorbed was negatively affected. This may be explained by the electrostatic repulsion force generated between the positive surface charge of CC (pH < pH_{PZC} = 5.8) and the cationic dye (CV). The same results was obtained in a later study, when we have used the same adsorbent, cedar cone, for elimination of cationic dye Rhodamine B from aqueous solution. The adsorption was minimal at low pH, since the electrostatic repulsive force created between the positive surface charge of CC and cationic dye [24].

In the pH range between 2 and 5.5 (5.5 is the pH of CV solution without modification) the cedar cone surface is steel positively charged (pH < pH_{PZC}) and the dye is cationic, which should increase the repulsive forces between the adsorbate and the adsorbent and therefore a decrease in the rate of dye elimination. However, we observed an increase in the amount of dye adsorbed from 87.53 to an maximum of 99.62 at pH of 5.5, which can maybe due to another phenomenon other than electrostatic forces like chemo-sorption.

Beyond pH equal to 5.5, the elimination rate decreases until reach a value of 92.19% at very basic pH (pH = 12). This decrease in the dye removal rate is probably due to the increase in repulsive forces between the negatively charged surface of CC, since pH > pH_{PZC}, and the cationic dye, trend was found by Brião et al. [25]. In addition, the amount of H⁺ present in the solution decreases as the pH increases, reducing the competition between them and the dye to occupy active adsorption sites [26]. The optimal pH given almost a total elimination of dye is the pH of CV solution (without modification) which is 5.5.

### 3.5 Isotherm adsorption

The adsorption isotherms are generally used for the design and determination of the interaction mechanisms existing between the adsorbate and the adsorbent at equilibrium [27]. However, the adsorption isotherms of crystal violet by cedar cones, were studied at temperatures of 298, 308
and 318 K, for different concentrations of dye. The results obtained are illustrated in Fig. 8.

The isotherms obtained show that the variation of $q_e$ as a function of the equilibrium concentration $C_e$ gives a curve of concavity turned down which makes it compatible with the "L-type" isotherm (normal Langmuir) [28]. This result can be explained by the existence of weak lateral interactions [28].

To describe better the adsorption process, the experimental data were fitted using isothermal models of Langmuir and Freundlich. Langmuir isotherm model describe quantitatively the formation of a monolayer adsorbate on the outer surface of the adsorbent, and after that, no further adsorption takes place [29, 30]. Freundlich isotherm model describes biosorption onto a heterogeneous surface [31]. The mathematical expression of Longmuir and Freundlich are summarized in Table 2. The model parameters of Langmuir and Freundlich equation were evaluated by non-linear regression method. For the determination of the best fitting isotherm to the experimental data, we consider the value of regression coefficient ($R^2$), and the sum square error function (SSE) which is represented as follows:

$$
SSE = \sum_{i=1}^{n} (q_{e,\text{calc}} - q_{e,\text{meas}})^2
$$

where $q_{e,\text{meas}}$ is the experimental value, $q_{e,\text{calc}}$ is the calculated value, $n$ is the number of data points in the experiment.

The dimensionless equilibrium parameter $R_L$ (4) indicates the nature of the shape of the isotherm accordingly [2, 6]:

$$
R_L = \frac{1}{1 + K_L C_0}
$$

where $C_0$ is the initial concentration of dye (mg/L), and $K_L$ (L/mg) is the Langmuir constant. The $R_L$ is used to evaluate the adsorption behavior of adsorbate onto adsorbent, if:

- $R_L > 1$ unfavorable adsorption;
- $0 < R_L < 1$ favorable adsorption;
- $R_L = 0$ irreversible adsorption;
- $R_L = 1$ linear adsorption.

Referring to Figs. 9 and 10 and the results regrouped in Table 2, the coefficient of correlation ($r^2$) determined by Freundlich model is greater or equal to 0.991, which show the good linearity and good agreement between the experimental and simulated non-linear fitting curve, with very small value of error function ($\approx \pm 69 \times 10^{-2}$).

The coefficient of correlation determined by Langmuir equation (Table 2) (≥ 0.97), show that this model can also fitted the experimental data, but it is feebler than that obtained by Freundlich model. Moreover, the value of error function obtained by non-linear regression of Langmuir is more or less greater ($\pm 2.307$). This allow us to concluded that the Freundlich model provide best fit to the

| Type      | Non-linear equation | Parameters          | Value      | SSE     |
|-----------|---------------------|---------------------|------------|---------|
| Langmuir  | $Q_e = \frac{Q_m C_e}{1 + K_L C_e}$ | $Q_m$(mg/g) | 13.646 ± 2.307 |
|           |                     | $K_L$(L/mg)        | 0.146 ± 0.044 |
|           |                     | $R^2$              | 0.970 –     |
| Freundlich| $Q_e = K_F C_e^{1/n}$ | $K_F$ (mg/g) (L/mg)$^{1/n}$ | 0.435 ± 0.069 |
|           |                     | $n$                | 0.717 ± 0.044 |
|           |                     | $R^2$              | 0.991 –     |

![Table 2 Langmuir and Freundlich isotherm parameters obtained by non-linear fitting](image)
equilibrium adsorption data compared by the Langmuir one. Similar result was reported in the literature, where the Freundlich model fit more better the experimental data then Langmuir, it’s about the study of CV adsorption on magnetic chitosan nanocomposite [32] and the adsorption of CV on waste materials [33].

The 1/n value > 1 indicates the favorable adsorption of dye onto adsorbent surface [2]. The value of separation factor  $R_L$ calculated at initial concentration of dye of 50 mg/L is equal to 0.77 (0 < $R_L$ < 1), which means that the CV adsorption onto CC was favorable.

4 Kinetic of adsorption

In order to examine the adsorption kinetics of CV on CC, the pseudo-first and pseudo second order model were applied to the kinetic experimental data. The pseudo-first order model, developed by Lagergren, is the first rate equation describing the adsorption kinetics of an adsorbent-adsorbent pair. It is based on the amount adsorbed. The adsorption rate at a time t is proportional to the difference between the quantity adsorbed at the equilibrium $q_e$ and that adsorbed at the instant t [34] and is represented as:

$$\frac{dq}{dt} = K_1 (q_e - q_t) \quad (5)$$

with: $K_1$: Speed constant of pseudo first order (1/min).

The integration of the equation for the initial conditions $q_t = 0$ to $t = 0$ gives the Eq. (6):

$$Ln(q_e - q_t) = Lnq_e - K_1 t \quad (6)$$

The amount of equilibrium adsorbed solute $q_e$ and the pseudo-first order rate constant $K_1$ are determined experimentally by plotting of $Ln (q_e - q_t)$ versus t.

The pseudo-second order adsorption rate established by Blanchard [35] also depends on the amount adsorbed at equilibrium. Is expressed in the form:

$$\frac{dq}{dt} = K_2 (q_e - q_t) \quad (7)$$

with: $K_2$: the pseudo second order rate constant (g/mg.min).

The integration of Eq. (7) with the limiting conditions $q_t = 0$ to $t = 0$ takes the linear form as described by equation:

$$\frac{1}{q_t} = \frac{1}{K_2 q_e^2} + \frac{1}{q_e} t \quad (8)$$

The plot of $1/q_t$ against t gives a linear relationship for the applicability of the second-order kinetic, with a slope of $1/(K_2 q_e^2)$ and an ordinate at the origin of $1/q_e$.

Fig. 10 Non-linear fitting of Freundlich isotherm model for the adsorption of CV by CC

Fig. 11 Plot of the linear form of the pseudo-first-order kinetic model at $T = 298$ K

Fig. 12 Plot of the linear form of the pseudo-second-order kinetic model at $T = 298$ K
The modeling of the adsorption kinetics of CV by CC by Lagergren and Blanchard equations for different adsorbate concentrations are presented in Figs. 11 and 12. The pseudo-first and second-order rate constants $K_1$, $K_2$, the predicted $q_e$ values, and the corresponding correlation coefficients $R^2$ were given in Table 3.

According to the results of Table 3, for the kinetic model of pseudo first order, the correlation coefficients $R^2$ are acceptable they are greater than 0.90 with an exception at the concentration of 10 mg/L ($R^2 = 0.48$), and the theoretical adsorption capacity is much lower than that obtained experimentally. This is suggests the not applicability of Lagergren model.

The adsorption kinetics can be analyzed by the Blanchard expression. The plot of $1/q_t$ as a function of time $t$ gives a linear curve. Based on the correlation coefficients of the Blanchard equation (almost equal to 1) and the values of theoretical maximum adsorption capacities which are comparable with the experimental values. This allows us to say that the kinetic adsorptions of CV by CC are pseudo-second-order model.

| Model                  | Initial dye concentration (mg/L) | 10     | 25     | 50     | 75     | 100    | 150    | 175    | 200    |
|------------------------|----------------------------------|--------|--------|--------|--------|--------|--------|--------|--------|
| Pseudo-first order     |                                  |        |        |        |        |        |        |        |        |
| $K_1$ (1/min)          | 0.027                            | 0.848  | 0.060  | 0.050  | 0.063  | 0.045  | 0.068  | 0.052  |
| $q_{e,th}$ (mg/g)      | 0.07                             | 1.558  | 0.692  | 1.209  | 2.250  | 4.512  | 5.340  | 5.275  |
| $q_{e,exp}$ (mg/g)     | 0.39                             | 0.99   | 2.0    | 2.9    | 3.9    | 5.89   | 6.82   | 7.71   |
| $R^2$                  | 0.48                             | 0.91   | 0.92   | 0.91   | 0.96   | 0.98   | 0.98   | 0.98   |
| Pseudo-second order    |                                  |        |        |        |        |        |        |        |        |
| $K_2$ (g/mg min)       | 0.39                             | 1.78   | 0.29   | 0.13   | 0.07   | 0.02   | 0.036  | 0.027  |
| $q_{e,th}$ (mg/g)      | 0.41                             | 1.01   | 2.02   | 2.97   | 4.00   | 6.19   | 7.08   | 8.04   |
| $q_{e,exp}$ (mg/g)     | 0.39                             | 0.99   | 2.00   | 2.91   | 3.9    | 5.89   | 6.83   | 7.77   |
| $R^2$                  | 0.97                             | 0.99   | 0.99   | 0.99   | 0.99   | 0.99   | 0.99   | 0.99   |

The CC used in this study, do not necessitate an additional pretreatment such as activation before applications of adsorption possess to give a high capacity for CV. Therefore, the adsorbent is estimated to be economically feasible for removal of CV dye from aqueous solutions.
