ABSTRACT

In this study we present the first results from multi-wavelength Hubble Space Telescope (HST) observations of the Galactic globular cluster (GC) NGC 2808 as an extension of the Hubble Space Telescope UV Legacy Survey of Galactic GCs (GO-13297 and previous proprietary and HST archive data). Our analysis allowed us to disclose a multiple-stellar-population phenomenon in NGC 2808 even more complex than previously thought. We have separated at least five different populations along the main sequence and the red giant branch (RGB), which we name A, B, C, D, and E (though an even finer subdivision may be suggested by the data). We identified the RGB bump in four out of the five RGBs. To explore the origin of this complex color–magnitude diagram, we have combined our multi-wavelength HST photometry with synthetic spectra, generated by assuming different chemical compositions. The comparison of observed colors with synthetic spectra suggests that the five stellar populations have different contents of light elements and helium. Specifically, if we assume that NGC 2808 is homogeneous in [Fe/H] (as suggested by spectroscopy for Populations B, C, D, E, but lacking for Population A) and that Population A has a primordial helium abundance, we find that populations B, C, D, E are enhanced in helium by $\Delta Y \sim 0.03$, 0.03, 0.08, 0.13, respectively. We obtain similar results by comparing the magnitude of the RGB bumps with models. Planned spectroscopic observations will test whether Population A also has the same metallicity, or whether its photometric differences with Population B can be ascribed to small [Fe/H] and [O/H] differences rather than to helium.

Key words: globular clusters: individual (NGC 2808) – stars: Population II

1. INTRODUCTION

Recent studies, based on multi-wavelength photometry, have revealed that the color–magnitude diagram (CMD) of all Galactic globular clusters (GCs) so far explored (Piotto et al. 2015, hereafter Paper I) is made of distinct sequences of stars that can be traced continuously from the bottom of the main sequence (MS) up to the tip of the red giant branch (RGB) and through the horizontal branch (HB) and the asymptotic giant branch (AGB). These sequences stand in contrast to the traditional view of GCs as the best example of simple stellar populations, i.e., made of stars born all at the same time and with the same chemical composition, confirming previous findings of CN variations in MS and RGB stars (Cannon et al. 1998; Grundahl et al. 1998; Grundahl 1999).

The Hubble Space Telescope UV Legacy Survey of Galactic GCs is a Hubble Space Telescope (HST) project to observe 54 GCs through the filters F275W, F336W, F438W of the Wide Field Camera 3 (WFC3) on board HST (see Paper I). This data set complements the existing F606W and F814W photometry from the Advanced Camera for Surveys (GO-10775, Sarajedini et al. 2007; Anderson et al. 2008) and is specifically designed to map multiple stellar populations in GCs.

NGC 2808 is one of the most intriguing Galactic GCs in the context of multiple stellar populations. It hosts a multimodal MS (D’Antona et al. 2005; Piotto et al. 2007; Milone et al. 2012a; Paper I), and exhibits a multimodal HB (Sosin et al. 1997; Bedin et al. 2000; Dalessandro et al. 2011) and RGB (Lee et al. 2009; Monelli et al. 2013; Paper I). Spectroscopy has shown star-to-star variations of several light elements and lithium, and an extended Na–O anticorrelation (Norris & Smith 1983; Carretta et al. 2006, 2010; Gratton et al. 2011; Carretta 2014; Marino et al. 2014; D’Orazi et al. 2015). These observations have been interpreted with multiple populations of stars with different helium abundance, from primordial abundance, $Y \sim 0.246$, up to extreme enhancement, $Y \sim 0.38$ (e.g., D’Antona et al. 2002, 2005; Piotto et al. 2007; Milone et al. 2012a). Evidence of helium enhancement in NGC 2808 has also been confirmed by direct measurements of helium-rich stars along the RGB and the HB (Pasquini et al. 2011; Marino et al. 2014).

While previous studies on multiple MSs in NGC 2808 were based on visual or near-infrared photometry, in this paper we extend the study to the ultraviolet. The ultraviolet region of the spectrum is indeed very powerful in the study of multiple stellar populations with different chemical composition. Molecular bands, such as OH, NH, CH, and CN, affect the ultraviolet and blue wavelengths, which are thus sensitive to populations with different C, N, and O compositions (Milone et al. 2012b; Paper I).

In this paper we use multi-wavelength ultraviolet and visual photometry (from Paper I) of stars in a field centered on NGC 2808 in order to identify multiple stellar populations in...
the CMDs. The behavior of multiple sequences in appropriate CMDs made with different combinations of colors and magnitudes will provide unique information on the helium and light-element content of the different stellar populations of this extreme GC.

The paper is organized as follows. In Section 2 we present the data and the data reduction. In Section 3 we analyze the CMDs and investigate multiple populations along the RGB and the MS. Helium and C, N, O abundances of the stellar populations are inferred in Section 4 from multiple MS and RGB locations in the CMD. The bumps of multiple RGBs of NGC 2808 are analyzed in Section 5, while Sections 7 and 8 are dedicated to the HB and the AGB. A discussion will follow in Section 9.

2. DATA AND DATA REDUCTION

In our study of NGC 2808 we have used archival and proprietary images taken with the Wide Field Channel of the Advanced Camera for Surveys (WFC/ACS) and the Ultraviolet and Visual Channel of the Wide Field Camera 3 (UVIS/WFC3) on board the Hubble Space Telescope (HST). Table 1 summarizes the data sets.

| Instrument | Date       | N x Exposure Time | Filter | Program | PI       |
|------------|------------|-------------------|--------|---------|----------|
| ACS/WFC    | 2004 May 5 | $6 \times 340$ s  | F475W  | 9899    | G.Piotto |
| ACS/WFC    | 2006 Aug 9 and Nov 2 | $20 + 2 \times 350 + 2 \times 360$ s | F475W | 10922   | G. Piotto |
| ACS/WFC    | 2006 Aug 9 and Nov 1 | $10 s + 3 \times 350 + 3 \times 360$ s | F814W | 10922   | G. Piotto |
| ACS/WFC    | 2006 Jan 1  | $23 + 5 \times 300$ s | F606W | 10775   | A. Sarajedini |
| ACS/WFC    | 2006 Jan 1  | $23 + 5 \times 370$ s | F814W | 10775   | A. Sarajedini |
| WFC3/UVIS  | 2013 Sep 8–9 | $12 \times 985$ s | F275W | 12605   | G. Piotto |
| WFC3/UVIS  | 2013 Sep 8–9 | $6 \times 650$ s | F336W | 12605   | G. Piotto |
| WFC3/UVIS  | 2013 Sep 8–9 | $6 \times 97$ s | F438W | 12605   | G. Piotto |

3. THE MULTIPLE PHOTOMETRIC COMPONENTS ALONG THE CMD OF NGC 2808

As already discussed in Section 1, previous studies based on ACS/HST and ground-based photometry have shown that NGC 2808 has at least a triple MS (Piotto et al. 2007; Milone et al. 2012a) and a broadened RGB (Lee et al. 2009; Monelli et al. 2013; Paper I). An inspection of the large number of CMDs that we derived from six-band photometry immediately reveals that NGC 2808 is even more complex than initially thought, and hosts more than three stellar populations.

A visual example of its complexity is provided by the CMDs in Figure 1. This figure shows several diagrams, after the quality selection and the differential-reddening correction described in the previous section were applied. To derive some of the diagrams of Figure 1 we have defined the pseudo-magnitudes $m_{F533W}$, $m_{F275W}$, $m_{F814W}$ = ($m_{F336W} - m_{F275W}$ + $m_{F814W}$) and $m_{F275W}$, $m_{F336W}$, $m_{F814W}$ = ($m_{F275W} - m_{F336W}$ + $m_{F814W}$), which allow us to better distinguish multiple sequences along the RGB and the MS. An inspection of these CMDs immediately suggests that both the RGB and MS are made of multiple sequences, which look discrete in the $m_{F275W}$ versus $m_{F814W}$, $m_{F275W}$, $m_{F336W}$, $m_{F814W}$ versus $m_{F275W}$ – $m_{F336W}$, and $m_{F336W}$, $m_{F275W}$, $m_{F814W}$ versus $m_{F275W}$ – $m_{F336W}$ diagrams. We also observe a widely spread subgiant branch (SGB) in the $m_{F275W}$ versus $m_{F336W}$ – $m_{F438W}$ CMD as shown in the upper-right inset of Figure 1. In the following we discuss the observed morphology of the CMD at various evolutionary stages: the RGB, MS, AGB, and HB.

3.1. The Quintuple RGB

Along the RGB, the behavior of multiple populations dramatically changes from one CMD to another. In order to investigate this phenomenon, in Figure 2 we compare the $m_{F814W}$ versus $m_{F275W}$ CMD of RGB stars (upper-left panel) and of the $m_{F814W}$ versus $m_{F336W}$ – $m_{F438W}$ CMD (upper-right panel). The insets show the Hess diagrams for stars in the magnitude interval with 14.5 < $m_{F814W}$ < 17.7 where multiple RGBs are clearly visible. Multiple stellar populations manifest themselves as four separate sequences in $m_{F275W}$ – $m_{F814W}$, while the $m_{F336W}$ – $m_{F438W}$ color distribution is more broadened and only two RGBs can be recognized.

In order to compare the two CMDs, we used the procedure introduced by Milone et al. (2015, hereafter Paper II) in their study of multiple populations in M2, and illustrated in Figure 2 for the case of NGC 2808. For that purpose, we drew two fiducial lines in each CMD. The blue and red fiducials mark the bluest and reddest envelopes of the RGB, respectively, and have been derived as follows. We have divided the RGB portion with $m_{F814W}$ > 14.8 into intervals of 0.2 magnitudes in
the F814W band. For each interval, we have determined the 4th
and the 96th percentiles of the
F275W - F814W
or
F336W - F438W
color distribution and the median
F814W
magnitude. The points corresponding to the 4th percentile and
the median magnitude have been interpolated with a cubic
spline to derive the blue
fiducial, while the red
fiducial has been
similarly derived. Due to small number statistics it is not
possible to infer robust estimates of the RGB envelopes with
this method at brighter luminosities. Therefore, the portions of
the blue and red lines in the magnitude interval with
F814W < 14.8 have been derived by hand by trying to follow
the blue and red envelopes of the RGB, respectively.

Then we have verticalized the two CMDs in such a way that
the blue and red fiducials translate into vertical lines with
abscissa −1 and 0, respectively. To do this, we defined for each
star:

\[ \Delta_X = \left[ \frac{(X - X_{\text{blue fiducial}})}{(X_{\text{red fiducial}} - X_{\text{blue fiducial}})} \right] - 1 \]

where

\[ X = (m_{F275W} - m_{F814W}), (m_{F336W} - m_{F438W}) \]

and

\[ X_{\text{blue fiducial}} \text{ and } X_{\text{red fiducial}} \]

are obtained by subtracting the color of the fiducial at the corresponding F814W magnitude from the color of each star. The verticalized
m_{F814W}
versus \Delta_F^{N}_{F275W,F814W}
and
m_{F814W}
versus \Delta_F^{N}_{F336W,F438W}
diagrams are plotted in the
lower-left panels of Figure 2. RGB stars in NGC 2808 are
clustered around distinct values of \Delta_F^{N}_{F336W,F438W} and
\Delta_F^{N}_{F275W,F814W}, as shown in the bottom-right panel of Figure 2.

As previously discussed by Anderson et al. (2008, see their
Section 8.1), F814W photometry of bright RGB stars is less
accurate than that of the remaining RGB stars because it has
been derived by using saturated stars (see Anderson et al. 2008
for details). Indeed, multiple sequences are less evident above
the gray dashed lines in the lower-left panels of Figure 2.
Dashed lines are placed at
m_{F814W} = 14.68. To investigate
whether the distinct sequences can also be detected along the
brightest RGB segment or not, we have marked stars with
m_{F814W} < 14.68 with red dots in the lower panels of Figure 2.
The distribution of these bright RGB stars on the
F336W,F438W
versus
F275W,F814W
plot shows that they share the same color
distribution as the fainter RGB stars.

To further investigate the stellar populations along the RGB,
in the upper-right panel of Figure 3 we plot the \Delta_F^{N}_{F336W,F438W}
versus \Delta_F^{N}_{F275W,F814W}
Hess diagram. At least five main clumps of RGB stars are clearly visible. These are selected by eye and
designated A, B, C, D, and E and are colored green, orange,
yellow, cyan, and blue, respectively (see the lower-left panel).
These color codes will be consistently used in the paper. RGB-
A–E contain (5.8 ± 0.5)%,(17.4 ± 0.9)%,(26.4 ± 1.2)%,(31.3 ± 1.3)% and (19.1 ± 1.0)% of the total number of RGB stars with
12.5 < m_{F814W} < 17.70, respectively. In Section 3.3 we show that populations A–E have different chemical composition.

Figure 1. \(m_{F275W}\) vs. \(m_{F275W} - m_{F814W}\) CMD of NGC 2808. The \(m_{F275W,F336W,F814W}\) against \(m_{F275W} - m_{F336W}\) (bottom-left inset), \(m_{F336W,F275W,F814W}\) against
\(m_{F275W} - m_{F336W}\) (bottom-right inset), and \(m_{F275W} vs. m_{F336W} - m_{F438W}\) (upper-right inset) diagrams highlight multiple sequences along the RGB, the
MS, and the SGB, respectively.
The $F_{275W},F_{814W}$ and $F_{336W},F_{438W}$ distributions of RGB stars are shown in the upper-left and lower-right panel of Figure 3, respectively. Black histograms represent the whole sample of RGB stars shown in the lower-left panel, while the distributions of the five distinct RGBs are plotted with shaded colored histograms. The $F_{275W},F_{814W}$ and $F_{336W},F_{438W}$ distributions exhibit significant differences. The histogram distribution of $F_{275W},F_{814W}$ clearly shows three main peaks at $-0.9$, $-0.6$, and $-0.3$. The first and second clumps are mainly composed of population-E and population-D stars, respectively, while the third peak is a mix of both population-B and population-C stars. A less populous peak, corresponding to population A, is located at $F_{275W},F_{814W} \sim 0.0$. In contrast, the $F_{336W},F_{438W}$ distribution looks bimodal. Most of the stars of populations C, D, and E have $F_{336W},F_{438W} > -0.5$ and determine the main peak at $F_{336W},F_{438W} \sim -0.2$. A second peak, mostly composed of population-B stars, is located around $F_{336W},F_{438W} \sim -0.8$.

In addition we note that:
1. Populations B and C are mixed in the $\Delta F_{275W,F814W}$ color range while they have distinct $F_{336W,F438W}$ values, with population-B stars having also smaller $F_{336W,F438W}$ values.

2. Population-A stars have larger $F_{275W,F814W}$ than both populations B and C. The color order is different in $F_{336W,F438W}$, where the histogram of population-A stars is located between the histograms of populations B and C.

3. Since the analyzed RGB stars cover the same F814W magnitude interval and have similar $m_{F336W}$ and $m_{F438W}$ magnitudes, their photometric errors are similar. We note that the $\Delta N_{F336W,F438W}$ spread for populations B and C ($\sigma_{\Delta F336W,F438W}^{NB} = 0.13 \pm 0.01$ and $\sigma_{\Delta F336W,F438W}^{NC} = 0.16 \pm 0.01$) is significantly larger than the spread observed for stars of populations A, D, and E ($\sigma_{\Delta F336W,F438W}^{ND} = 0.10 \pm 0.02$, $\sigma_{\Delta F336W,F438W}^{NE} = 0.10 \pm 0.01$, and $\sigma_{\Delta F336W,F438W}^{NF} = 0.10 \pm 0.01$). This fact indicates that the $m_{F336W} - m_{F438W}$ color spread observed for populations B and C is, in part, intrinsic and that both group B and group C are not simple stellar populations. In fact, a visual inspection of the Hess diagram of Figure 3 suggests that both groups consist of two clumps of stars that are clustered around $\Delta F_{336W,F438W} \sim -0.85, -0.65$ (group B) and $-0.2, -0.1$ (group C), thus suggesting that stars in both groups B and C do not have homogeneous chemical composition. More data are needed to establish whether these clumps correspond to distinct stellar populations.

The causes of the “discreteness” of multiple populations as observed in the CMD and two-color diagram of some GCs are still unknown, and have been associated with distinct bursts of star formation (see Renzini 2008 for a critical discussion). The referee has pointed out that the distinct bumps in the diagrams of Figure 3 could indicate that some abundances are favored over the others and suggested a possible connection between the abundances of stars in the distinct clumps of NGC 2808 and NGC 6752.
metal mixtures that are consistent with equilibrium CN or equilibrium ON cycling. While this hypothesis deserves some investigation that is beyond the purposes of our paper, we emphasize that the evidence of discrete populations in NGC 2808 provides a strong constraint for any model of formation and evolution of stellar populations in GCs.

At the request of the referee and of the Statistical Editor of this journal, Prof. Eric Feigelson, we have used the Mccluster CRAN package in the public-domain R statistical software system to estimate how many groups are statistically significant. This package is based on the method described in detail in the monograph “Finite Mixture Models” by McLachlan & Peel (2000). It performs the maximum likelihood fits to different numbers of stellar groups, and evaluates the number of groups by the Bayesian information criterion (BIC) penalized likelihood measure for model complexity.

To do this it uses several different assumptions about shape and size of the different populations in a plot such as that shown in Figure 3. For each shape and size that we adopted for the populations, we assumed a number, \( N \), of stellar populations from 1 to 20 and estimated a BIC for each combination. We obtain the best BIC value (BIC = 1784) for \( N = 6 \) under the assumption that the stellar populations have equal shapes but variable volume and orientations (VEV). The second most likely explanation (BIC = 1778) corresponds to \( N = 6 \) but assumes equal shape, VEV. The third best value (BIC = 1776) corresponds to a VEV assumption and seven stellar populations. All the three best models assume ellipsoidal distributions.

Results from this statistical analysis support the conclusion that our observations of NGC 2808 are consistent with more than five groups of stars, and that group C hosts more than one stellar population. The third best BIC value suggests that also the group B is not consistent with a simple population. Thus, the statistical analysis confirms what was already pretty evident from a purely visual inspection of the plots. In the following, we will study the five most evident stellar populations, A–E.

### 3.2. Multiple Populations Along the MS

The MS of NGC 2808 exhibits different patterns in CMDs based on different photometric bands, in close analogy with what we observe along the RGB. This is shown in the upper panels of Figure 4 where we compare the \( m_{F814W} \) versus \( m_{F275W} - m_{F814W} \) (left panel) and the \( m_{F814W} \) versus \( m_{F336W} - m_{F438W} \) (right panel) CMDs of MS stars with 19.6 < \( m_{F814W} \) < 20.7. The MS looks discrete in \( m_{F275W} - m_{F814W} \) with three distinct components, in contrast with the \( m_{F336W} - m_{F438W} \) color distribution, which looks broadened without any evidence for discrete sequences.

In order to identify the different stellar populations, we have verticalized the MSs by following the same recipe as introduced in Section 3.1 for the RGB, and using the fiducial lines drawn in the upper-panel CMDs. The \( m_{F814W} \) versus \( \Delta_{N}^{N_{C}} \) in the upper-left and lower-middle panels, while the lower-right panel shows \( \Delta_{N}^{F_{336W},F_{438W}} \) against \( \Delta_{N}^{F_{275W},F_{814W}} \).

The pseudo-color \( C_{F275W,F336W,F438W} = (m_{F275W} - m_{F336W}) - (m_{F336W} - m_{F438W}) \) defined by Milone et al. (2013) is another valuable tool to identify multiple populations in GCs. To better distinguish the distinct MSs and RGBs of NGC 2808 we show in the left panel of Figure 5 the \( m_{F814W} \) versus \( C_{F275W,F336W,F438W} \) pseudo CMD for this cluster. The red and the blue lines superimposed on this diagram are the envelopes of the MS and the RGB, and have been determined with the same procedure as in Section 3.1. These two fiducials are used to verticalize the MS and the RGB. The verticalized \( m_{F814W} \) versus \( \Delta_{C}^{N_{C}} \) diagram for RGB and MS stars is plotted in the middle panels. An inspection of these figures reveals that three distinct sequences are present along the RGB, while only two MSs are visible. In the right panels of Figure 5 we plot \( \Delta_{N}^{F_{275W},F_{814W}} \) against \( \Delta_{C}^{F_{275W},F_{336W},F_{438W}} \) for RGB (upper panel) and MS stars (lower panel).

In order to identify stellar populations along the MS, we exploit the \( \Delta_{N}^{F_{336W},F_{438W}} \) versus \( \Delta_{N}^{F_{275W},F_{814W}} \) diagram and the \( \Delta_{N}^{F_{275W},F_{336W},F_{438W}} \) versus \( \Delta_{N}^{F_{275W},F_{814W}} \) Hess diagram shown in the lower-left and upper-right panels of Figure 6, respectively. The distribution of MS stars in this plane is similar to that observed for the RGB, as better highlighted by the Hess diagram in the upper-right panel Figure 6. There are at least four groups of MS stars that we denote B, C, D, and E, and color orange, yellow, cyan, and blue, in the bottom-left and rightmost panels, in close analogy with what was done for the RGB. Colors introduced in this figure will be used consistently hereafter. It is noticeable that the separation among the four groups is less clear for the MS than in the case of the RGB. This could be due to fact that colors of these relatively hot MS stars are less sensitive to light-element variations than the RGB. Indeed we have shown in our previous papers that the color difference between multiple MSs and RGBs is due, apart from helium, to different strengths of the molecular bands between the distinct populations of stars (Marino et al. 2008; Milone et al. 2012a). In particular, the OH band and the CH G-band, which are stronger in the stellar population with the same chemical composition as halo field stars of the same metallicity, mainly fall in the F275W and the F438W bands, respectively, while the NH band, which is weaker in stars of this population, mainly affects the F336W magnitude. Population A is not clearly distinguishable, even if a stellar overdensity can be recognized in the Hess diagram at \( \Delta_{N}^{F_{275W},F_{814W}} \), \( \Delta_{N}^{F_{336W},F_{438W}} \) \( \sim \) (0.0; −0.5). We tentatively associate these stars with population A and color them green in the lower-left panel. In the upper-middle and upper-right panels of Figure 6 we compare the \( \Delta_{N}^{F_{275W},F_{336W},F_{438W}} \) versus \( \Delta_{N}^{F_{275W},F_{814W}} \) Hess diagrams for RGB and MS stars, while, in the corresponding lower panels, we show the position of Populations A–E in this plane.

In order to further investigate whether MS-A stars correspond to a distinct stellar population or whether their position in the \( \Delta_{N}^{F_{275W},F_{814W}} \) versus \( \Delta_{N}^{F_{336W},F_{438W}} \) plane is entirely due to measurement errors, we adopt a procedure introduced by Anderson et al. (2009) and illustrated in Figure 7. In the left panel we show the \( m_{F814W} \) against \( m_{F475W} - m_{F814W} \) CMD from Milone et al. (2012a). The red and blue lines superimposed on the CMD are the fiducials of the red and blue MSs and are drawn by hand. The verticalized \( m_{F814W} \) versus \( \Delta_{N}^{F_{475W},F_{814W}} \) diagram is plotted in the central panel, while the right panel shows \( \Delta_{N}^{F_{275W},F_{814W}} \) versus \( \Delta_{N}^{F_{275W},F_{814W}} \). Stars in common with this paper are marked with colored circles.

Photometry by Milone et al. (2012a) comes from ACS/WFC images, and hence represents a different data set than the WFC3 ones used in this paper. If the large \( \Delta_{N}^{F_{275W},F_{814W}} \) value for stars in the group A derived from UVIS/WFC3 photometry...
is entirely due to photometric errors, then these stars have the same probability of having either small or large $\Delta N_{F814W}$ derives from WFC/ACS. The systematically large $\Delta N_{F814W}$ value of stars in group A, shown in the right panel of Figure 7, is evidence that they belong to a distinct stellar population.

### 3.3. Chemical Composition of Stellar Populations

Spectroscopy of RGB stars has revealed that NGC 2808 exhibits a very extended sodium–oxygen anticorrelation, with [O/Fe] spanning a range of more than 1 dex (Carretta et al. 2006). Twenty-seven stars analyzed by Carretta and collaborators are also included in our photometric sample, thus providing useful information on the chemical composition of the stellar populations we have identified in the previous sections. Carretta’s stars are marked with large symbols in Figure 8 where we reproduce the $\Delta N_{F336W,F438W}$ versus $\Delta N_{F275W,F814W}$ diagram of Figure 3 (left panel), the Na–O anticorrelation from Carretta et al. (2006, middle panel), and the Mg–Al anticorrelation from Carretta (2014, right panel). Noticeably, stars in the B, C, D, and E stellar groups defined in this paper have almost the same iron content within $\sim$0.05 dex but populate different regions of the Na–O plane. The average elemental abundance for stars of population B, C, D,
and E is listed in Table 2, where we also provide the dispersion, $\sigma$, and the number of stars, $N$, in each population with available abundances. The error is estimated as $\sigma$ divided by the square root of $N - 1$. Unfortunately, there are no population-A stars in the sample analyzed by Carretta et al. collaborators.

The five population-B stars in common with the Carretta et al. sample all have primordial Na and O ([Na/Fe] $\sim$ 0.0, [O/Fe] $\sim$ 0.0).
and blue MSs. Middle panel: verticalized $m_{F814W}$ vs. $\Delta_{F475W,F814W}$ diagram. Stars in common with this paper are represented with colored circles. Right panel: $\Delta_{F475W,F814W}^{N}$ (from this paper) vs. $\Delta_{F475W,F814W}^{D}$ (from Milone et al. 2012a).

Figure 7. Left panel: $m_{F814W}$ against $m_{F475W} - m_{F814W}$ from the ACS/WFC photometry published by Milone et al. (2012a). Red and blue lines are the fiducials of the red and blue MSs. Middle panel: verticalized $m_{F814W}$ vs. $\Delta_{F475W,F814W}$ diagram. Stars in common with this paper are represented with colored circles. Right panel: $\Delta_{F475W,F814W}^{N}$ (from this paper) vs. $\Delta_{F475W,F814W}^{D}$ (from Milone et al. 2012a).

$\Delta \approx 0.3$, and the ten population-C stars are slightly enhanced in sodium ($[\text{Na/Fe}] \approx 0.2$ dex) and depleted in O ($[\text{O/Fe}] \approx 0.15$ dex) with respect to population B. Population-E stars all have very low oxygen abundance and high $\text{Na/Fe}$, while population-D stars are consistent with an intermediate chemical composition.

More recently, Carretta (2014) has determined Mg and Al abundances for 31 RGB stars in NGC 2808 from UVES spectra and detected a very extended Mg–Al anticorrelation with three distinct groups of stars with different contents of magnesium and aluminum. There are five stars in common with Carretta (2014), all Mg-rich and Al-poor and with similar $\text{Mg/Fe}$ ratio. On average, the two population-C stars are slightly more Al-rich than the three population-B stars by $\sim 0.2$ dex, but a larger sample is needed to establish the significance of this difference.

Carretta et al. (2010) have defined three groups of stars in NGC 2808 on the basis of their Na and O abundances. A “primordial” component containing all stars with $[\text{Na/Fe}] \lesssim 0.19$, an “extreme” one with $[\text{O/Na}] < 0.9$, and an “intermediate” component with intermediate values of Na and O. Our findings show that the component that they designated “primordial” contains at least two different stellar populations, i.e., B and C, thus suggesting that NGC 2808 has experienced a very complex star formation history.

4. CARBON, NITROGEN, OXYGEN, AND HELIUM OF STELLAR POPULATIONS FROM MULTIPLE MSS AND RGBS

In order to infer the helium abundance of each stellar population of NGC 2808 we adapted the method introduced by Milone et al. (2012b) in their study of 47 Tucanae to the case of NGC 2808. This method is based on the comparison between the observed colors of the multiple sequences and the predictions from appropriate isochrones and the relative synthetic spectra. In this section we will exploit the same technique to estimate the abundance of C, N, and O for the five populations of NGC 2808.

In Sections 3.1 and 3.2 we have used two-color diagrams from appropriate combinations of F275W, F336W, F438W, and F814W magnitudes to identify five stellar populations along the RGB and the MS. For simplicity, in the following we will indicate as MS-A–E and RGB-A–E the groups of MS and RGB stars of populations A–E. To analyze the behavior of multiple sequences, we have plotted $m_{F814W}$ against $m_{F438W} - m_{F814W}$, where $X = F275W$, F336W, F438W, F475W, and F606W, and determined the MS and the RGB fiducials of each population.

Results are shown in Figure 9 where we have plotted the RGB and the MS fiducials in the upper and lower panels, respectively. MS-E exhibits the bluest $m_{X} - m_{F814W}$ color in all the CMDs of Figure 9. Population D has the second bluest MS, while MS-A is redder than the other MSs in all plots. MS-B and MS-C are placed between MS-A and MS-D and their relative position changes from one CMD to another. MS-C is slightly bluer than MS-B in $m_{F275W} - m_{F814W}$ and $m_{F438W} - m_{F814W}$ colors but is redder than MS-B in $m_{F336W} - m_{F814W}$. MS-B is almost superimposed on the MS-C in the $m_{F475W} - m_{F814W}$ and $m_{F606W} - m_{F814W}$ colors. Lower panels of Figure 9 show that the $m_{F275W} - m_{F814W}$, $m_{F438W} - m_{F814W}$, and $m_{F606W} - m_{F814W}$ color orders of multiple RGBs and MSs are similar. In the $m_{F814W}$ against $m_{F336W} - m_{F814W}$ CMD, RGB-E and RGB-B share the bluest colors, while RGB-A, RGB-C, and RGB-D define a red sequence.

In order to further investigate multiple MSs and RGBs, we have calculated the $m_{X} - m_{F814W}$ color difference between each MS (or RGB) fiducial and MS-B (or RGB-B) fiducial at a reference magnitude $m_{F814W}^{\text{CUT}}$ that we indicate as $\Delta (m_{X} - m_{F814W})$. Figure 10 shows $\Delta (m_{X} - m_{F814W})$ as a function of the central wavelength of the X filter for MS (left panel, $m_{F814W}^{\text{CUT}} = 20.25$) and RGB fiducials (right panel, $m_{F814W}^{\text{CUT}} = 16.25$). We repeated this procedure for $m_{F814W}^{\text{CUT}} = 19.80, 19.95, 20.10, 20.40,$ and 20.55 for the MS and for $m_{F814W}^{\text{CUT}} = 15.25, 15.75, 16.75,$ and 17.25 for the RGB. We find that the color separation between populations A and B increases with the color baseline. In the case of both populations D and E, $\Delta (m_{X} - m_{F814W})$ grows monotonically for $X = F606W$, $X = F475W$, and $X = F438W$, then it drops for $X = F336W$ and reaches its maximum for $X = F275W$. Population C exhibits almost the same color as population B apart from the case of $X = F336W$, where population C has negative $\Delta (m_{X} - m_{F814W})$.

7 Due to the small number of RGB stars for which F475W is available we have not used this filter for the study of multiple RGBs.
Table 2

| Pop. | Abundance | σ | # |
|------|-----------|---|---|
|      | [O/Fe]    |   |   |
| A    | ...       | ...| 0 |
| B    | 0.30 ± 0.05 | 0.11 | 5 |
| C    | 0.16 ± 0.04 | 0.11 | 9 |
| D    | −0.37 ± 0.02 | 0.02 | 3 |
| E    | −0.66 ± 0.09 | 0.12 | 3 |
|      | [Mg/Fe]   |   |   |
| A    | ...       | ...| 0 |
| B    | 0.38 ± 0.02 | 0.03 | 3 |
| C    | 0.35 ± 0.12 | 0.12 | 2 |
| D    | ...       | ...| 0 |
| E    | ...       | ...| 0 |
|      | [Al/Fe]   |   |   |

| B    | 0.05 ± 0.02 | 0.03 | 3 |
| C    | 0.23 ± 0.13 | 0.13 | 2 |
| D    | ...       | ...| 0 |
| E    | ...       | ...| 0 |
|      | [Na/Fe]   |   |   |
| A    | ...       | ...| 0 |
| B    | 0.03 ± 0.06 | 0.13 | 5 |
| C    | 0.21 ± 0.03 | 0.09 | 10 |
| D    | 0.40 ± 0.04 | 0.09 | 6 |
| E    | 0.79 ± 0.08 | 0.18 | 6 |
|      | [Fe/H]    |   |   |
| A    | ...       | ...| 0 |
| B    | −1.13 ± 0.02 | 0.04 | 5 |
| C    | −1.08 ± 0.02 | 0.06 | 10 |
| D    | −1.12 ± 0.02 | 0.04 | 6 |
| E    | −1.10 ± 0.03 | 0.08 | 6 |

Note. Results are inferred by matching photometry with high-resolution-spectroscopy measurements by Carretta et al. (2006) and Carretta (2014).

It has been shown that variations in the abundance of both helium and some light elements (e.g., C, N, O) are responsible for multiple MSs and RGBs in GCs (e.g., Marino et al. 2008; Sbordone et al. 2011; Milone et al. 2012b; Dotter et al. 2015). In a few GCs multiple sequences are also due to iron variations (e.g., Pancino et al. 2000; Piotto et al. 2005; Marino et al. 2012; Paper II). To investigate the effect of C, N, O, iron, and helium on the CMD of NGC 2808 we started to compute synthetic spectra that we used as reference for population-B stars (from here on “reference spectrum”). We used BaSTI isochrones (Pietrinferni et al. 2004, 2009) to estimate the effective temperature ($T_{\text{eff}} = 5619 \, \text{K}$) and the surface gravity ($\log g = 4.56$) at $m_{\text{F814W}} = m_{\text{F814W}}^\text{cut}$ for a MS star with helium ($Y = 0.278$). We assumed for NGC 2808 a metallicity of $[\text{Fe/H}] = −1.14$ (Harris 1996, 2010 edition), an average reddening $E(B-V) = 0.19$ (Bedin et al. 2000) and a distance modulus ($m-M_V = 15.59$) (Harris 1996, 2010 edition). We computed a synthetic spectrum with $[\text{O/Fe}] = 0.3$, as derived for population B in Section 3.3 from Carretta et al. (2006) measurements, and $[\text{C/Fe}] = −0.3$, and $[\text{N/Fe}] = 0.5$ as inferred by Bragaglia et al. (2010) for one red-MS star analyzed in their paper. We assumed $Y = 0.278$ for population B.

We have also computed additional synthetic spectra for stars with the same F814W magnitude, but different chemistry. We denoted these spectra as “comparison spectra.” We assumed for each of them the same chemical composition as the reference spectrum, but different abundances for He, C, N, O, and Fe.

Since stars with the same luminosity in the F814W band, but different He or [Fe/H], have also different temperature and gravity (e.g., Sbordone et al. 2011; Cassisi et al. 2013), when the content of helium and iron are varied, atmospheric parameters are changed accordingly, as predicted by BaSTI isochrones. Specifically, in order to determine the appropriate value of $T_{\text{eff}} = T_{\text{eff}}^* \text{for a star with magnitude } m_{\text{F814W}} = m_{\text{F814W}}^* \text{and a given content of helium } Y = Y^*$, we have calculated the

---

8 This choice for the helium content of population B is somehow arbitrary, and in practice adopted to avoid a helium content formally smaller than the primordial one for population A. We note that, in this section, we measure helium differences among the different populations, not absolute helium values. A different choice of primordial helium content for the reference population would have a negligible impact on the estimated $\Delta Y$. 

---

Figure 8. Left panel: reproduction of the $\Delta_{\text{F275W,F438W}}^N$ vs. $\Delta_{\text{F275W,F814W}}^N$ diagram of Figure 3. Stars for which spectroscopic measurement are available are marked with large symbols. Middle panel: sodium–oxygen anticorrelation for RGB stars of NGC 2808 from Carretta et al. (2006). Large orange, yellow, cyan, and blue dots indicate spectroscopic targets of populations B, C, D, and E, respectively. Stars for which only [Na/Fe] measurements are available have been arbitrarily plotted at [O/Fe] = 1.1. No population-A stars are present in the Carretta et al. sample. Right panel: magnesium–aluminum anticorrelation from Carretta (2014). Population-B and population-C stars are indicated with orange and yellow triangles, respectively.
values of $T_{\text{eff, isochrone}}$ at $m_{\text{F814W}} = m_{\text{F814W}}^{*}$ from each available isochrone and estimated $T_{\text{eff}}^*$ by linearly interpolating the value of $T_{\text{eff, isochrone}}$ that corresponds to $Y = Y^*$. Interpolations are done within the various available isochrones with helium $Y_{\text{isochrone}} = 0.246, 0.28, 0.30, 0.33, 0.35, 0.40$.

The adopted range of light elements and iron matches observations from high-resolution spectroscopy (Carretta et al. 2006; Bragaglia et al. 2010; Gratton et al. 2011; Marino et al. 2014). The differences in temperature and chemical composition between the comparison and the reference spectrum are indicated in the left panels of Figure 11.
Figure 11. Left panels: the ratio between the flux of some comparison spectra and the reference spectrum for a MS-B star at $m_{F814W}^\text{ST} = 20.25$ is plotted as a function of the wavelength. Each comparison spectrum has the same chemical composition as the reference spectrum apart from the abundance of one element, as indicated in each panel. When $Y$ and [Fe/H] are changed the atmospheric parameters of the comparison spectrum are also varied accordingly, as indicated. Right panels: color difference ($\Delta(m_X - m_{F814W})$) between the comparison spectra and the reference spectrum (see text for details).
We used ATLAS12 (Castelli 2005; Kurucz 2005; Sbordone et al. 2007) and SYNTHE codes (Kurucz 2005) to account for the adopted chemical composition and to perform the spectral synthesis in the wavelength interval between 2000 and 10000 Å. Synthetic spectra have been integrated over the transmission curves of the F275W, F336W, F438W filters of UVIS/WFC3 and the F475W, F660W, F814W filters of ACS/WFC, and, for each spectrum, we calculated the color $m_X - m_{F814W}$.

Results are illustrated in the right panels of Figure 11 and provide an indication of the effect of varying C, N, O, Fe, and He on the observed colors. Left panels show the flux ratio between the comparison spectrum and the reference spectrum of MS stars with $m_{F814W} = 20.25$. The corresponding $\Delta (m_X - m_{F814W})$ color differences are plotted in the right panels.

In the top-left panels of Figure 11 we analyze two comparison spectra sharing the same atmospheric parameters and chemical composition as the reference spectrum, but depleted in carbon. A difference in [C/Fe] of 0.4, as observed for red- and blue-MS stars by Bragaglia et al. (2010), mainly affects $m_{F438W} - m_{F814W}$ and marginally changes the other colors studied in this work. On the other hand, variations in [N/Fe] produce a large $m_{F435W} - m_{F814W}$ difference (panel (b)). Because of the effect of the OH, NH, and CH bands on the different photometric bands discussed in Section 3.2, changing [O/Fe] mainly affects $m_{F275W} - m_{F814W}$ and $m_{F335W} - m_{F814W}$ colors, with negligible changes for visual colors (panel (c)).

In panel (d) we changed C, N, and O in such a way that the overall C+N+O abundance in the reference and in the comparison spectra remains unchanged. In this case we have large differences in $m_{F275W} - m_{F814W}$ and $m_{F335W} - m_{F814W}$.

As shown by Sbordone et al. (2011), helium variation marginally affects the atmospheric structure and the resulting flux distribution. However, stars with the same luminosity but different helium have different effective temperature (see Figure 1 by Sbordone et al. 2011, as an example). For this reason, helium variation results in a difference of both visual and ultraviolet colors as shown in panel (e), with the $m_{F275W} - m_{F814W}$ and $m_{F335W} - m_{F814W}$ color differences being significantly larger than those in $m_{F438W} - m_{F814W}$ and $m_{F475W} - m_{F814W}$. Also variations in [Fe/H] affect all the colors studied in this paper, but, in this case, the differences corresponding to visual and ultraviolet colors are similar (panel (f)).

We conclude that the F275W and F336W bandpasses are very sensitive to the detailed chemical abundance of the cluster stars, therefore maximizing the separation among the various sub-sequences due to the variations of light elements and helium. Specifically, the F275W band is mainly affected by oxygen variations via the strength of the OH molecular bands, while F336W is mostly sensitive to nitrogen via the NH molecular bands. In contrast, the optical colors ($m_{F438W} - m_{F814W}$, $m_{F475W} - m_{F814W}$, and $m_{F660W} - m_{F814W}$) are less affected by C, N, O variations, but are very sensitive to temperature variations associated with differences in helium. In addition, a difference in [Fe/H] of less than 0.1 dex, as inferred for NGC 2808 from high-resolution spectroscopy by Carretta et al. (2006), corresponds to small color variations.

Having demonstrated that optical and ultraviolet colors are very sensitive to helium and light-element variations, we have estimated the chemical composition of population E. To do this we have adopted the procedure described above to calculate synthetic spectra with different helium abundances, with $Y$ ranging from 0.246 to 0.400 in steps of $\Delta Y = 0.001$, and $[C/Fe]$, [N/Fe], and [O/Fe] from −2.0 to 2.0 dex in steps of $\Delta [C/Fe] = 0.1$; $\Delta [N/Fe] = 0.1$, and $\Delta [O/Fe] = 0.1$. The values of $T_{eff}$ and log $g$ corresponding to different $Y$ have been derived from isochrones as described above. We used chi-square minimization to determine the best fit between the synthetic colors and observations. The helium, carbon, nitrogen, and oxygen abundances derived from the best-fit model are listed in Table 3 for different values of $m_{F814W}$ together with its effective temperature and gravity.

Multi-wavelength photometry of RGB stars is also very sensitive to C, N, O, and helium. To better constrain the chemical composition of the five stellar populations of NGC 2808, we have extended the method described above for MS stars to the RGB. We note that the values of [C/Fe] and [N/Fe] adopted for population-B stars come from spectroscopy of MS stars. When a star ascends the RGB it is affected by mixing phenomena that alter the original surface abundance of C and N, while keeping constant C + N (e.g., Iben 1967). To account for this phenomenon, we followed the recipe by Milone (2015) and assumed that the reference spectrum for a RGB-B star has a 0.3 dex lower C abundance than that inferred from the MS by Bragaglia et al. (2010). Nitrogen abundance has been determined by assuming that the sum C + N remains constant and corresponds to $[N/Fe] = 0.62$ dex. The adopted variation approximately matches the value predicted by Angelou et al. (2011) for multiple stellar populations in M3.

Results for populations A, C, D, and E are illustrated in Figure 12. The upper-left panel shows the flux ratio between the best-fitting MS-E comparison spectrum and the reference spectrum for $m_{F814W} = 20.25$, while the normalized throughput of the filters used in this paper is plotted in the middle-left panel. In the lower-left panel we overplotted the color differences derived from synthetic spectra on the observed color difference between MS-B and MS-E of Figure 10 (blue dots). Right panels compare the observed MS and RGB color distance between population B and populations A, C, D, and E of Figure 10 and the color differences from the best-fit models of Tables 3 and 4.

From the analysis of multiple MSs, we can infer that populations D and E are highly helium-enhanced by $\Delta Y \sim 0.11$ and $\Delta Y \sim 0.06$, respectively, and are both strongly enhanced in N and depleted in O. Population C shares almost the same helium as population B ($\Delta Y \sim 0.01$) and is more nitrogen-rich and more oxygen-poor than the latter. Under the assumption that populations A and B have the same metallicity, population A would have a lower helium content than population B, by $\Delta Y \sim 0.03$, while it would have almost the same nitrogen.

As suggested by the referee, we have also repeated the helium abundance estimates using only the $m_{F660W} - m_{F814W}$ color difference between each sequence and isochrones with different helium abundance, as this color is not significantly affected by light-element variations (Sbordone et al. 2011). The results are fully consistent with those found from the analysis above, within helium differences less than 0.005.

Results on the estimated compositions of the different populations are shown in Figure 13, where we used colored circles to illustrate the differences in carbon (left panel), nitrogen (middle panel), and oxygen (right panel) as a function of the helium variation between populations A, C, D, and E.
Table 3 (Continued)

Best-fit Atmospheric Parameters and Relative Abundances for Synthetic Spectra of MS Stars at Different Values of mF814W

| Population | Teff | log g | ΔY | Δ[C/Fe] | Δ[N/Fe] | Δ[O/Fe] |
|------------|------|-------|----|---------|---------|---------|

Note: We assumed for the MS-B: Y = 0.278, [C/Fe] = -0.3, [N/Fe] = 0.5, [O/Fe] = 0.3. See text for details.

5. RGB Bump of the Stellar Populations

In a simple stellar population the luminosity of the RGB bump is an indicator of its metallicity, age, helium abundance, and C + N + O content (e.g., Cassisi & Salaris 1997; Bono et al. 2001; Bjork & Chaboyer 2006; Pietrinferni et al. 2009, Di Cecco et al. 2010; Cassisi et al. 2011). In a CMD with multiple sequences as in a GC, the distinct RGB bumps can provide information on the age and the chemistry of the various subpopulations. In the specific case of NGC 2808, Nataf et al. (2013) found that this GC hosts a broadened RGB bump. Although their photometry was not corrected for differential reddening, and therefore they did not distinguish the different bumps, they suggested that this peculiar shape of the RGB bump is likely due to multiple stellar populations with different helium content. In this section we investigate the bump of the RGBs identified in Section 3.1 and infer helium abundance by comparing their observed luminosity with theoretical predictions.

The mF814W against mF275W − mF814W and the mF814W against mF336W − mF438W Hess diagrams of RGB stars plotted in Figure 14 show that the RGB bump of NGC 2808 exhibits a complex structure. The Hess diagrams reveal multiple bumps, with different F814W luminosities that are associated with the different stellar populations. Lower-left and lower-middle panels of Figure 14 reproduce the same mF814W versus Δ^N_{F275W,F814W} and mF814W versus Δ^N_{F336W,F438W} diagrams of Figure 3, but zoomed-in around the RGB bump. In the lower-right panel we plot the histogram of the distribution in mF814W for all the RGB stars shown in the left and middle panels (black histogram). Colored histograms represent the mF814W population B as inferred from multi-wavelength photometry of multiple MSs (upper panels) and multiple RGBs (lower panels). Overall, we see a correlation between nitrogen and helium, while both [C/Fe] and [O/Fe] anticorrelate with Y. Noticeably there is a large difference of nitrogen between populations B and C associated with a small helium variation.

In the right panel of Figure 13 colored triangles are obtained from the average oxygen abundance determined in Section 3.3 from high-resolution spectroscopy of RGB stars by Carretta et al. (2006) for populations B, C, D, and E. In general, results from spectroscopy and photometry are in agreement at the one-sigma level, although we note that photometry from this paper systematically predicts slightly smaller [O/Fe] variations for populations C, D, and E.
distribution of stars for all the stellar populations of NGC 2808 we have identified with the exception of population A, which includes too few members for an accurate identification of the bump magnitude. Histograms have been obtained by adapting the naive estimator (Silverman 1986). Briefly, we first defined a regular sample of points ($m_{F814W}$), ranging from 14.7 to 15.4, with $m_{F814W}^{i+1} - m_{F814W}^{i} = 0.2$ mag. Then we have extracted the histogram by associating with each point, $m_{F814W}$, the number of RGB stars with $m_{X} - m_{F814W} < m_{X}^{i} + \omega/2$. We assumed $\omega = 0.013$ mag.

In order to obtain the $m_{F814W}$ luminosity of the bumps, we used the following procedure. We started to estimate by eye a raw position for the bump luminosity in each histogram and selected all the points within 0.15 F814W magnitudes of this position. We least-squares fitted these points with a Gaussian and considered the position of the center of the best-fitting Gaussian ($m_{F814W, bump}$) as a new estimate for the bump luminosity. Finally, we selected all the points of the histogram within 2$\sigma$ (where $\sigma$ is the width of the best-fitting Gaussian) from $m_{F814W, bump}$, for a new least-squares Gaussian fit. This later determination of $m_{F814W, bump}$ corresponds to our best estimate of the $m_{F814W}$ luminosity of the bump. Errors on $m_{F814W, bump}$ are determined by bootstrapping with replacements performed 1000 times on the sample of analyzed RGB stars. The error bars indicate the 1$\sigma$ (68.27th percentile of the bootstrapped measurements. Colored dots in the left and middle panels of Figure 14 mark the positions of the bumps for the four stellar populations in the $m_{F814W}$ versus $F275W,F814W$ and $m_{F814W}$ versus $F336W,F438W$ diagrams. We repeated the same procedures to estimate the bump position in the F275W, F336W, F438W, and F814W bands. The RGB-bump magnitudes ($m_{X, bump}$, $X = F275W$, F336W, F438W, F606W, and F814W) for four stellar populations are listed in Table 5, while in Figure 15 we show the difference between the RGB-bump magnitudes of populations C, D, and E and the RGB-bump magnitude of population B against the central wavelength of the X filter.

In four bands, namely F275W, F438W, F606W, and F814W, the RGB-bump brightness anticorrelates with $F275W,F814W$ (e.g., lower-left panel of Figure 14). Population E hosts the brightest bump. The RGB bumps of populations B and C share almost the same luminosity, and the population-D bump is brighter than those of populations B and C. The magnitude separation among the bumps is nearly constant in F438W, F606W, and F814W but increases by a factor of $\sim 2$ in F275W, as shown in Figure 15. We also note that the order of
We assumed for the RGB-B:

| E | ... | 0.005 | ± 0.1 | ± 0.1 | 0.0 | 0.1 |

Note. We assumed for the RGB-B: $Y = 0.278$, $[\text{C/Fe}] = -0.6$, $[\text{N/Fe}] = 0.62$, $[\text{O/Fe}] = 0.3$. See text for details.
6. COMPARISON AMONG THE \( \Delta Y \) FROM THE DIFFERENT METHODS

Figure 17 shows the difference between the \( \Delta Y \) estimated from the RGB and the MS (upper panel), the bump location and the RGB (middle panel), and the bump location and the MS (lower panel). We note that there is a small discrepancy between the \( \Delta Y \) from the MS and the RGB for populations D and E, though within \( \lesssim 2\sigma \). The \( \Delta Y \) from the RGB is in fair agreement with the value calculated using the bump luminosity (within 1\( \sigma \)). The comparison of the middle panel of Figure 17 would favor a younger isochrone.

Note that several authors have found that NGC 2808 has a younger (10\%–15\%) age than the average age of intermediate-metallicity clusters (Rosenberg et al. 1999; De Angeli et al. 2005; VandenBerg et al. 2013; Milone et al. 2014). The comparison between the \( \Delta Y \) from the MS and the bump is somewhat less satisfactory, though still within 1–2\( \sigma \) (depending on the adopted models). Again, a younger age seems to be favored. A discussion of the origin of these discrepancies is beyond the purposes of the present paper and will be postponed to a future paper.

7. THE HORIZONTAL BRANCH

Among Galactic GCs, NGC 2808 hosts one of the most extended HBs, which spans an extreme \( m_{F275W} - m_{F336W} \) color range (\( L_2 \approx -0.9 \), Milone et al. 2014). The distribution of stars along the HB of this cluster exhibits three significant gaps, which separate four groups of HB stars: a red HB hosting about half of the total number of HB stars, and three distinct segments of blue HB stars (Sosin et al. 1997; Bedin et al. 2000; Piotto et al. 2007). The CMD shown in Figure 1 confirms this complex morphology.

Spectroscopy of HB stars in NGC 2808 further reveals that stars with different light-element abundances are distributed along different HB regions. Red HB stars are Na-poor and O-rich, while blue HB stars are depleted in oxygen and enhanced in sodium (Gratton et al. 2011; Marino et al. 2014).

The sodium distribution of red HB stars is bimodal, with Na-rich stars having, on average, bluer \( B - V \) and \( U - V \) colors (Marino et al. 2014). The histogram of the [Na/Fe] distribution for red HB stars from Marino et al. (2014) is reproduced in the upper-left panel of Figure 18, where we have colored red and blue the two stellar populations identified by these authors. For six HB stars in the HST field of view sodium abundances are available from Marino and collaborators. There is a clear anticorrelation between [Na/Fe] and \( m_{F275W} \), with sodium-poor stars having also fainter luminosity in F275W as shown in the lower-left panel of Figure 18.

To further investigate the connection between stellar populations with different sodium abundance and the red HB we combine optical and ultraviolet photometry. Since \( m_{F275W} - m_{F336W} \) and \( m_{F336W} - m_{F435W} \) colors are very efficient in separating stellar populations along the red HB of GCs, in the right panel of Figure 18 we plot the \( m_{F275W} \) versus \( c_{F275W,F336W,F435W} \) Hess diagram for NGC 2808. The fact that stars with different [Na/Fe] populate different regions of the \( m_{F275W} \) versus \( c_{F275W,F336W,F435W} \) diagram supports the conclusions by Gratton et al. (2011) and Marino et al. (2014) that the red HB of NGC 2808 is not consistent with a simple stellar population.

The inset shows a zoom around the red HB. The distribution of stars along the HB is multimodal, with three main groups of stars clustered around \( c_{F275W,F336W,F438W} \sim 1.15, \ 1.25, \) and 1.33 as highlighted by the histogram distribution of the pseudo-color \( c_{F275W,F336W,F438W} \) shown in the inset. An appropriate comparison with HB theoretical models is required to disentangle the effects of mass loss, evolved stars, and multiple stellar populations on the morphology of the red HB and to understand whether the three bumps correspond to distinct

![Figure 13. Variation of carbon (left), nitrogen (middle), and oxygen (right) as a function of the helium variation for the five populations of NGC 2808. Elemental variations are calculated with respect to average abundance of population-B stars. Results obtained from multiple MSs and RGBs are plotted in the upper and lower panels, respectively. Filled circles indicate the He, C, N, O relative abundances inferred from multi-wavelength photometry, while the values of \( \Delta[O/Fe] \) inferred from spectroscopy of RGB stars are represented with triangles. For clarity, spectroscopic measurements are shifted by \( \Delta Y = 0.01 \).](image-url)
populations, but this is beyond the purposes of the present paper.

8. MULTIPLE POPULATIONS ALONG THE AGB

Figure 19 illustrates our analysis of the AGB of NGC 2808. The upper panels show a collection of $m_{F814W} - m_{X}$ versus $m_{F814W}$ CMDs zoomed around the AGB ($X = F275W$, F336W, F438W, F606W). The 51 stars with $m_{F814W} > 13.5$ that, on the basis of their positions in these CMDs, are probable AGBs have been marked with colored symbols. The lower-left panel shows the $m_{F438W}$ versus $C_{F275W,F814W}$ diagram, where AGB stars are distributed along three distinct sequences. This feature is a signature of multiple stellar populations along the AGB. We defined three groups of AGB$_I$, AGB$_II$, and AGB$_III$ stars that include 25, 11, and 15 stars, colored red, aqua, and magenta, respectively. These colors are used consistently in Figure 19. AGB$_III$ is bluer than the remaining AGB stars in all the CMDs, while AGB$_I$ are slightly bluer than AGB$_I$ in all the CMDs apart from the $m_{F814W}$ versus $m_{F336W} - m_{F814W}$ CMD where these two groups of AGB stars are almost overlapping. The $m_{F275W}$ versus $m_{F275W} - m_{F336W}$ CMD in the lower-right panel of Figure 19 shows that AGB$_III$ are brighter than the other AGB stars in F275W and that AGB$_II$ are, on average, brighter than AGB$_I$.

Theoretical models predict that hot HB stars would undergo a transition to an extended blueward nose excursion and exhibit bluer colors than the progeny of cold HB stars when reaching the AGB (e.g., Gingold 1976). It is tempting to speculate that the group of AGB$_II$ stars is the progeny of helium-rich HB, AGB$_I$ stars have primordial helium, and the AGB$_III$ belongs to a population with intermediate composition. The AGB$_I$ stars host $49 \pm 11\%$ of the total number of AGB stars in agreement, within the large error bar, with the total fraction of the three helium-poorer RGB-A, RGB-B, RGB-C stars, which include half of the RGB stars of NGC 2808. The fractions of AGB$_II$ and AGB$_III$ stars are $22 \pm 6\%$ and $29 \pm 8\%$, respectively. These numbers only vaguely resemble the fraction of RGB-D ($\sim 31\%$) and RGB-E ($\sim 19\%$), though we admit there is some arbitrariness in selecting the AGB members of the three groups.
NGC 2808 as part of the metricy to investigate multiple stellar populations in the GC results can be summarized as follows. The RGB-bump magnitude of population B, C, D, and E, respectively, and the RGB-bump magnitude of population B (m$_{X,bump}^B$), respectively, and the RGB-bump magnitude of population B (m$_{X,bump}^B$).

We conclude that further analysis, possibly based on the synergy between spectroscopy and photometry, is needed to connect the triple AGB with the multiple RGBs of NGC 2808. Significantly, stars with extremely thin H-rich envelopes miss the AGB phase and move toward the white dwarf cooling sequence. It is not possible to firmly establish from the present data set if these “AGB Manque” stars are present in NGC 2808 or not.

9. DISCUSSION

In this paper we have used multi-wavelength HST photometry to investigate multiple stellar populations in the GC NGC 2808 as part of the Hubble Space Telescope UV Legacy Survey of Galactic GCs project (Piotto et al. 2015). Our basic results can be summarized as follows.

1. We have identified five distinct stellar groups along the RGB of NGC 2808, namely A, B, C, D, and E, which contain (5.8 ± 0.5)% (17.4 ± 0.9)% (26.4 ± 1.2)% (31.3 ± 1.3)% and (19.1 ± 1.0)% of the total number of RGB stars with 12.25 < m$_{F814W}$ < 17.70, respectively. The five stellar populations have been also detected along the MS although the separation between MS-A, MS-B, and MS-C is less evident than in the case of the RGB. We have found that the red MS discovered by Piotto et al. (2007) is composed of populations A, B, and C, while their middle and the blue MS correspond to populations D and E, respectively.

2. We have exploited high-resolution spectroscopy from the literature to infer the abundance of Na, O, Al, and Mg for the five stellar populations. First of all, we have identified the RGB-A–E stars for which chemical abundances from high-resolution spectroscopy are available. Specifically, Carretta et al. (2006) and Carretta (2014) have found large star-to-star variations of [Na/Fe], [O/Fe], [Al/Fe], and [Mg/Fe] and identified three groups of O-normal, O-poor, and O-super-poor stars. We have matched the sample by Carretta and collaborators with our multi-wavelength photometry and found that 32 of their stars belong to populations B, C, D, and E as defined in this paper.

Using the spectroscopic information, we found that population B has solar sodium-to-iron abundance ratio and is enhanced in oxygen ([O/Fe] ∼ 0.3 dex). Population C is enhanced in sodium ([Na/Fe] ∼ 0.2) and slightly depleted in oxygen by ∼−0.1 dex with respect to population B. Populations D and E are both sodium-rich and oxygen-poor and have [Na/Fe] ∼ 0.4 and [Na/Fe] ∼ 0.8, and [O/Fe] ∼ −0.4 and [O/Fe] ∼ −0.7, respectively. Unfortunately, no population-A RGB stars have spectroscopic information. Abundances of magnesium and aluminum are available only for three population-B and two population-C stars. All of them are distributed around [Mg/Fe] ∼ 0.4 and [Al/Fe] ∼ 0.1 with the two population-C stars being, on average, slightly enhanced in [Al/Fe] by ∼0.1 dex. A larger sample is mandatory to establish if such a difference in Al is significant or not.

3. We have inferred the content of helium, C, N, O for the five populations of NGC 2808. To do this, we have followed the method by Milone et al. (2012b) and compared the observed colors with predictions from synthetic spectra. We found that populations D and E are enhanced in helium by ∼0.06 and ∼0.11, respectively, with respect to the populations B and C, which share almost the same helium abundance. This helium difference follows from the assumption that populations A and B have the same metallicity. From this assumption it also follows that population A has ∼0.03 less helium than both populations B and C. Planned spectroscopic observations in particular of population-A stars may allow us to test this assumption, and indicate whether the photometric differences between these two populations can be ascribed to iron and oxygen differences, rather than to helium. If we assume that population A has primordial helium (Y = 0.246), our results indicate that population-E stars are highly helium-enhanced up to Y ∼ 0.39.

Note that it is the effect of variations in helium abundance on stellar temperatures that mostly causes optical and UV colors to change. Indeed stars with the same luminosity but different Y have different effective temperature and gravity. In contrast, helium has a marginal effect on the stellar atmosphere. (Sbordone et al. 2011).

The comparison of observed and synthetic colors allow us to also estimate the average abundance of C, N, and O for each stellar population. We found that populations C, D, and E are enhanced in nitrogen by ∼0.5, ∼0.6, and ∼0.8 dex with respect to population B, while population A has slightly lower nitrogen (∆N/Fe) ∼ 0.1) than population B. Both oxygen and carbon anticorrelate with nitrogen.

4. We have detected the RGB bump of populations B, C, D, and E. In visual filters, which are marginally affected by light-element variations, the bumps of populations B and C have almost the same luminosity, while the RGB bumps of populations D and E are ∼0.07 and ∼0.17 mag brighter. The comparison of the observed bump
luminosity with theoretical models suggests that populations D and E are more helium-rich than both populations B and C by \( \sim 0.03 \) and \( \sim 0.06 \) dex, respectively.

5. We confirm that the HB of NGC 2808 is multimodal with four main HB segments. In addition, we confirm that the red HB is inconsistent with a simple stellar population as suggested by the fact that the two groups of sodium-rich and sodium-poor stars identified by Marino et al. (2014) populate different regions along the red HB.

6. The AGB hosts three MSs that are well distinguished in the \( m_{F438W} \) versus \( C_{F275W,F336W,F438W} \) diagram. This finding indicates that the AGB of NGC 2808 hosts multiple stellar populations.

In conclusion, the most astonishing property of this cluster is certainly its extremely complex stellar populations, as illustrated in Figures 1 and 3. We have distinguished five discrete stellar populations, but a closer look at the Hess diagram shown in Figure 3 suggests that reality may be even more complex. Indeed, all five clumps appear to have some internal structure, as if each of them could further split into two components, or could have an internal spread in its photometric properties that may result from a small spread in chemical composition. This is particularly evident for populations B and C. We notice that our photometric data have an accuracy of \( \sim 0.01 \) mag, sufficient to resolve individual clumps, but to distinguish between an internal spread and a multiplicity would require a larger samples of stars.

The clear discreteness of the five (main) populations is a fact that every scenario for the formation of GCs must be able to account for. As emphasized in Paper I, this kind of discreteness is indeed a ubiquitous property among GCs and cannot be ignored. It suggests that star formation occurred in a sequence of discrete events interleaved by periods of inactivity while the chemical composition of the interstellar medium was changing. However, we postpone to a future paper of this collaboration a dedicated discussion as to whether the various proposed scenarios can comply with this and the other observational constraints illustrated in Paper I.

### Table 5

| X       | \( m_{X}^{bump} \) | \( m_{X}^{bump} \) | \( m_{X}^{bump} \) | \( m_{X}^{bump} \) |
|---------|---------------------|---------------------|---------------------|---------------------|

### Figure 16

Left panel: reproduction of the \( m_{F814W} \) vs. \( C_{F275W,F814W} \) diagram for RGB stars of Figure 2. Middle panel: zoom of left-panel diagram around the bump of population E, where RGB-E stars are marked with blue dots. Right panel: histogram of the \( F814W \) magnitude distribution. Gray error bars are Poisson errors while the red dashed–dotted line is the assumed luminosity function for the RGB (see text for details).
It also goes beyond the scope of this paper to try to identify in which temporal sequence the various multiple populations may have been generated, but we need to at least try to identify the first generation of this cluster. Population B is oxygen-rich and sodium-poor (see Figure 8) and also is rather populous (~17% of the total in our sample), so it is the obvious candidate for being the first generation. However, if this is the case, we have a problem with population A, which is redder than population B in both $m_{F275W} - m_{F814W}$ and $m_{F336W} - m_{F438W}$ and for which no spectroscopic abundances are available from Carretta et al. (2006) and Carretta (2014).

We have argued above that if Populations B and A were to have the same metallicity, then the helium abundance of population A should be lower than that of population B by ~0.03. Since no physical mechanism is known that could deplete the helium abundance below its Big Bang value on such a scale, one would be forced to consider population A as the first generation. This is quite unpalatable, as population A represents only ~6% of the whole population of the cluster. Even if A+B together are regarded as the first generation, still they make up only ~23% of the whole population sampled by WFC3 at the center of NGC 2808. However, as in the case of other clusters, the first generation may be less centrally concentrated than subsequent generations and a more extensive mapping of this cluster is required to measure the overall fractions of the various populations.

The alternative is to relax the assumption of these two populations having the same metallicity. Like in other clusters (e.g., M22, NGC 1851, M2, NGC 5286), a small fraction of the core-collapse supernovae from the first generation may have contaminated the interstellar medium while such a stellar population was still in the making. An increase of $[\text{Fe/H}]$ by

Figure 17. Upper panel: difference between the $\Delta Y$ estimated from the RGB and the MS for populations A, B, C, D, E. Middle panel: difference between the $\Delta Y$ coming from the bump location and the RGB. Lower panel: difference between the $\Delta Y$ coming from the bump location and the MS. We used two different isochrone sets and two different ages to estimate $\Delta Y$ from the magnitude of the bump.

Figure 18. Upper-left panel: histogram of the distribution of $[\text{Na/Fe}]$ for red HB stars (Marino et al. 2014). Lower-left panel: $m_{F275W}$ vs. $[\text{Na/Fe}]$. Right panel: $m_{F275W}$ vs. $C_{F275W,F336W,F438W}$ Hess diagram. The Hess diagram in the inset is a zoom around the red HB, and the histogram of the distribution in $C_{F275W,F336W,F438W}$ for red HB stars is also shown. Na-rich and Na-poor stars defined by Marino and collaborators are colored blue and red, respectively.
∼0.1–0.2 dex, associated with a parallel increase in oxygen as expected from core-collapse supernovae, could then account for the photometric differences between populations A and B. Our group is already engaged in high-resolution spectroscopic observations with GIRAFFE at the Very Large Telescope and spectra of stars in the five RGBs of NGC 2808 will be obtained soon. In particular, the abundances of iron, carbon, nitrogen, oxygen, and sodium will be measured for population A, hence assessing whether this interpretation is viable.

Moreover, it should be noticed that, although some authors have suggested that multiple sequences are associated with distinct generations of stars, the possibility that GCs have experienced multiple or prolonged events of star formation is still strongly debated. We refer to papers by D’Antona et al. (2005), Decressin et al. (2007), D’Ercole et al. (2008, 2010), Renzini (2008), Bastian et al. (2013), Cabrera-Ziri et al. (2014, 2015), Niederhofer et al. (2015) and references therein for critical discussion and for various scenarios and interpretations of multiple stellar populations.

We warmly thank David Yong, who has performed the statistical analysis with the Mc cluster CRAN package, described in Section 3.1 and Aaron Dotter and Bob Sharp for useful discussions on the statistical significance of the stellar populations. The anonymous referee and the Statistical Editor of this journal, Prof. Eric Feigelson, have provided several suggestions that have improved the quality of the paper. A. P. M. and H. J. acknowledge support by the Australian Research Council through Discovery Early Career Researcher Award DE150101816 and Discovery Project grant DP150100862. S. C. and G. P. acknowledge partial support by PRIN-INAF 2014. G. P. acknowledges partial support by Progetto di Ateneo (Università’ di Padova) 2014.

Figure 19. Upper panels: $m_{F814W}$ vs. $m_{X} - m_{F814W}$ CMDs of AGB and RGB stars in NGC 2808 ($X = F275W, F336W, F438W, F606W$). Lower panels: $m_{F438W}$ vs. $C_{F275W,F336W,F438W}$ (left) and $m_{F275W} - m_{F336W}$ CMD (right). Red, aqua, and magenta symbols represent the three groups of AGBI, AGBII, and AGBIII stars defined in the lower-left panel.
