Abstract

Intraductal neoplasms are important precursors to invasive pancreatic cancer and provide an opportunity to detect and treat pancreatic neoplasia before an invasive carcinoma develops. The diagnostic evaluation of these lesions is challenging, as diagnostic imaging and cytological sampling do not provide accurate information on lesion classification, the grade of dysplasia or the presence of invasion. Moreover, the molecular driver gene mutations of these precursor lesions have yet to be fully characterized. Fifty-two intraductal papillary neoplasms, including 48 intraductal papillary mucinous neoplasms (IPMNs) and four intraductal tubulopapillary neoplasms (ITPNs), were subjected to the mutation assessment in 51 cancer-associated genes, using ion torrent semiconductor-based next-generation sequencing. P16 and Smad4 immunohistochemistry was performed on 34 IPMNs and 17 IPMN-associated carcinomas. At least one somatic mutation was observed in 46/48 (96%) IPMNs; 29 (60%) had multiple gene alterations. GNAS and/or KRAS mutations were found in 44/48 (92%) of IPMNs. GNAS was mutated in 38/48 (79%) IPMNs, KRAS in 24/48 (50%) and these mutations coexisted in 18/48 (37.5%) of IPMNs. RNF43 was the third most commonly mutated gene and was always associated with GNAS and/or KRAS mutations, as were virtually all the low-frequency mutations found in other genes. Mutations in TP53 and BRAF genes (10% and 6%) were only observed in high-grade IPMNs. P16 was lost in 7/34 IPMNs and 9/17 IPMN-associated carcinomas; Smad4 was lost in 1/34 IPMNs and 5/17 IPMN-associated carcinomas. In contrast to IPMNs, only one of four ITPNs had detectable driver gene (GNAS and NRAS) mutations. Deep sequencing DNA from seven cyst fluid aspirates identified 10 of the 13 mutations detected in their associated IPMN. Using next-generation sequencing to detect cyst fluid mutations has the potential to improve the diagnostic and prognostic stratification of pancreatic cystic neoplasms.

Introduction

Intraductal neoplasms of the pancreas are cystic or mass-forming epithelial neoplasms that characteristically grow primarily within the ductal system [1] and include two main groups: intraductal papillary mucinous neoplasms (IPMNs) and intraductal tubulopapillary neoplasms (ITPNs).

IPMNs are precursor lesions to invasive adenocarcinoma, accounting for 5% of pancreatic neoplasms. Epithelial morphology and mucin expression patterns define four main histological subtypes of IPMN [2]: intestinal, gastric, oncocytic and pancreaticobiliary. Recent papers support the hypothesis of distinct pathways for carcinogenesis among the different IPMN subtypes [3,4].

Cancer is a fundamentally genetic disease, and IPMNs are no exception. IPMNs commonly harbour activating mutations in KRAS and GNAS, and inactivating mutations in RNF43, CDKN2A/p16 and TP53, and
less commonly mutations in *BRAF, PIK3CA, STK11* and *SMAD4* [5–12]. *TP53, CDKN2AP16* and *SMAD4* mutations and/or loss of expression are generally found in higher-grade lesions [13–15]. IPMNs are genetically heterogeneous [16], and different patterns of genetic alterations have been reported in the different morphological subtypes of IPMNs: Mohri *et al* [4] reported *KRAS* mutations as more prevalent in intestinal-type IPMN [4]; Xiao *et al* [17] identified *KRAS* and *BRAF* mutations and abnormal p53 immunolabelling in the oncocytic type, but less frequently than in the pancreateobiliary IPMN. Yamaguchi *et al* [18] analysed 15 gastric-type IPMNs, pyloric gland variant, which showed frequent mutations in *GNAS* and *KRAS* (60% and 80%, respectively). ITPN is a rare variant of pancreatic intraductal neoplasms recently defined as a distinct entity in the WHO classification [1]. A recent mutational analysis of 14 ITPNs detected *PIK3CA* mutations in three cases, and one case each with *KRAS* and *BRAF* mutations, while no *GNAS* mutation was detected, suggesting a different molecular origin for ITPN [12,18].

Massive parallel sequencing, also known as next-generation sequencing (NGS) or deep sequencing, can be customized to enable accurate detection of mutations in gene panels with limited DNA [19,20]. Such an approach represents a potent diagnostic complement to histopathological and immunophenotypical diagnosis [21].

In the present study we used targeted NGS to examine the mutational status of 51 cancer-related genes in 52 intraductal neoplasms of the pancreas. We also tested the diagnostic performance of NGS in cystic fluids from 10 patients with IPMN, supporting the use of NGS for classifying cyst type in clinical practice.

Materials and methods

Cases

A retrospective series of 52 pancreatic intraductal neoplasms from 51 surgically-treated patients (Table 1), including 48 IPMNs and four ITPNs, with one IPMN and one ITPN coexisting in the same patient, were retrieved from the ARC-Net biobank at Verona University Hospital (www.arc-net.it). The series included 40 fresh-frozen (FF) and 12 formalin-fixed paraffin-embedded (FFPE) tissues. IPMNs were classified according to WHO 2010 [1]. Dysplasia was graded as low (LG), intermediate (MG) and high grade (HG). In 10 intestinal-type IPMNs, cystic fluids were harvested from pancreatocystomy specimens with a fine needle syringe and stored at −80°C within 30 min of resection. Normal pancreatic tissues were used to determine the somatic or germline nature of mutations.

Ethics

The materials were collected under Program 853 protocol 298CE 15/02/02 and revised Program 1885 protocol 52438 23/11/2010, approved by the Verona University Hospital Ethics Committee. The protocols include informed consents from the patients.

DNA extraction and quantification

DNA was obtained from tissues after enrichment for neoplastic cellularity, using manual microdissection. DNA was extracted using the QiAamp DNA Mini Kit (Qiagen) from FFPE specimens and the QIAamp DNA FFPE Tissue Kit (Qiagen) from FFPE specimens. DNA from 250 μl cystic fluid was purified by adding 3 ml RLTM buffer (Qiagen) and then binding to an AllPrep DNA/RNA Mini Kit (Qiagen) columns and washed with 70% ethanol in an autosampler (Deming Lab, Alpignano, Italy). The quality of DNA was assessed using the NanoDrop (Invitrogen) and Qubit (Invitrogen) platforms [22]. The quality of DNA was further evaluated by PCR, using the BIOMED 2 PCR multiplex protocol [23].

Deep sequencing of multiplex PCR amplicons of 51 genes

Two multigene panels were used: the 50-gene Ion AmpliSeq Cancer Hotspot Panel v 2 (Life Technologies) and an AmpliSeq Custom Panel investigating seven genes. The former selected regions of the following 50 cancer-associated genes: *ABL1, AKT1, ALK, APC, ATM, BRAF, CDH1, CDKN2A, CSF1R, CTNNB1, EGFR, ERBB2, ERBB4, EZH2, FBXW7, FGFR1, FGFR2, FGFR3, FLT3, GNA11, GNAS, GNAQ, HNF1A, HRAS, IDH1, IDH2, JAK2, JAK3, IDH2, KDR/VEGFR2, KIT, KRAS, MET, MLH1, MPL, MLC2, MUC1, MUC4, MYC, MYD88, NFE2L2, NOTCH1, NQO1, NTRK1, NRAS, PI3KCA, PTEN, RAF1, RET, RNF43, SMAD4, SMARCA4, SRC, STK11, TERT, TFE3, TP53, TPS3*
NOTCH1, NPM1, NRAS, PDGFRA, PIK3CA, PTEF, PTPN11, RB1, RET, SMAD4, SMARCB1, SMO, SRC, STK11, TP53 and VHL. The custom panel was designed to target selected regions of six genes included in the previous panel (BRAF, CDKN2A, GNAS, KRAS, SMAD4 and TP53) and RNF43, which was not in the first panel. Details of the target regions for both panels are given in Table S1A, B (see supplementary material).

DNA samples (20 ng) were used for multiplex PCR amplification. Emulsion PCR was performed with the OneTouch DL or OneTouch2 systems (Life Technologies). The quality of the obtained library was evaluated by the Agilent 2100 Bioanalyzer on-chip electrophoresis (Agilent Technologies). Sequencing was run on the Ion Torrent Personal Genome Machine (PGM; Life Technologies), loaded with 316 (50-gene panel) or 318 chips (custom panel). Data analysis, including alignment to the hg19 human reference genome and variant calling, was done using Torrent Suite software v 3.2 and v 3.6 (Life Technologies). Filtered variants were annotated using SnpEff software v 3.1 and Ion Reporter software v 1.6 (Life Technologies). Alignments were visually verified using the Integrative Genomics Viewer (IGV v 2.2, Broad Institute).

PCR fragments were analysed by Sanger sequencing. PCR products were purified using Agencourt AMPure XP magnetic beads (Beckman Coulter), labelled with Big Dye Terminator v 3.1 (Applied Biosystems). Agencourt CleanSEQ magnetic beads (Beckman Coulter) were used for post-labelling purification. Sequence analysis was performed on an Applied Biosystems 3130xl Genetic Analyser.

**Immunohistochemistry**

IPMN tumour phenotypes were investigated according to the WHO classification [1] by applying antibodies to mucin core proteins: MUC-1 (clone DF3, 1:50; Abcam), MUC2 (clone Ccp58, 1:100; Novocastra Laboratories), MUC5AC (clone CLH2, 1:100; Novocastra Laboratories), and MUC6 (clone CLH5, 1:100; Novocastra Laboratories). The immunohistochemical expression of p53 (clone DO-1, prediluted; Immunotech), β-catenin (clone 15B8, 1:150; Sigma), CDKN2A/p16 (clone JC8, 1:100; Santa Cruz Biotechnology) and Smad4 (clone B-8, 1:200; Santa Cruz Biotechnology) was tested as a surrogate validation of the deep sequencing results.

**Statistical analysis**

Fisher’s exact test was used to compare mutational frequencies among IPMNs grouped according to either histological subtype or tumour grade. \( p < 0.05 \) was considered statistically significant.
Figure 2. Mutational profiles of matched non-invasive and invasive IPMN components identified by ion torrent sequencing. (A) Three cases (128 fp, 129fp and 138fp) presented a non-invasive intermediate-grade (IG) or high-grade (HG) dysplastic component and an invasive adenocarcinoma (K) component, both of which were analysed using the 50-gene Ampliseq Hotspot Cancer Panel; representative H&E images from case 138fp are presented (original magnifications ×2 and ×20). (B) For each pair of samples, the first column denotes mutations detected in IG or HG dysplastic samples and the second column represents mutations detected in cancer samples. Rows are the genes in which mutations were detected, and the orange bars represent the mutation. Seven mutations observed in the GNAS, KRAS, BRAF, and STK11 genes were common to both samples; three mutations were observed in only one of the matched lesions.

Table 2. Mutational profile of non-invasive and invasive components in three cases of IPMN with associated carcinoma

| Sample  | Subtype              | Lesion            | GNAS     | KRAS     | TP53     | BRAF     | STK11    | CDKN2A   | PTEN     |
|---------|----------------------|-------------------|----------|----------|----------|----------|----------|----------|----------|
| #128fpB| Intestinal HG dysplasia | R201H (38%) V14I (37%) K601E (33%) | 128fp    |
| #128fpA| Intestinal Colloid carcinoma | R201H (27%) V14I (32%) K601E (28%) | 128fp    |
| #129fpB| Intestinal HG dysplasia | G12V (42%) V227L (81%) Q171* (74%) | 128fp    |
| #129fpA| Intestinal Colloid carcinoma | G12V (16%) V227L (31%) | 128fp    |
| #138fpA| Pancreaticobiliary HG dysplasia | G12D (44%) V227L (81%) | 128fp    |
| #138fpB| Pancreaticobiliary Tubular carcinoma | G12D (23%) V227L (31%) | 128fp    |

IG, intermediate grade; HG, high grade. Mutated alleles percentages are shown in parentheses.

Results

Clinicopathological data

Fifty-two pancreatic intraductal neoplasms, comprising 48 IPMNs and four ITPNs, were retrieved from 51 patients, as one patient had two separate lesions, an IPMN and an ITPN (Table 1, Figure 1). Of the 52 lesions, 40 (77%) were in the pancreatic head and/or the uncinate process, nine (17%) in the pancreatic body/tail and three (6%) diffusely involved the gland. Macroscopically, 31 (60%) neoplasms were main-duct type, three (6%) branch-duct type and 18 (34%) combined-type. The 48 IPMNs were classified, according to WHO classification [1], into the following subtypes: 36 intestinal, six gastric, three pancreaticobiliary and three oncocytic. Invasive carcinoma was associated with the IPMN in 29 of 51 (57%) patients: 18 of the invasive cancers were colloid carcinomas and 11 were conventional tubular adenocarcinomas.

Tissues and cystic fluid subjected to sequencing

Non-invasive lesions from the 48 IPMNs were low-grade (LG) in three cases, intermediate-grade (IG) in 17 cases and high-grade (HG) in 28 cases. For three IPMNs (128fp, 129fp and 138fp), sufficient material was obtained from non-invasive and invasive neoplastic areas (Figure 2, Table 2; see also supplementary material, Table S2). One IPMN coexisted with an ITPN in the same patient (case 130fp); the two lesions were microdissected and analysed separately (Figure 3; see also supplementary material, Table S2). All four ITPNs showed HG dysplasia. In 10 intestinal-type IPMNs cystic fluid was available, and in seven of these (70%) an adequate library for sequencing was obtained.

Prevalence of driver gene mutations among the 50 genes of the AmpliSeq panel

An adequate library was obtained from all samples for subsequent sequencing. Mean 100× coverage of 98.9% with a mean read length of 110 bp was obtained in the 40 FF samples and mean 100× coverage of 98.5% with a mean read length of 105 bp was obtained in the 12 FFPE samples.

GNAS and KRAS mutations were the most prevalent alterations, found in 39/52 (75%) and 24/52 (46%) lesions, respectively. GNAS and/or KRAS mutations were identified in 45/52 (87%) cases; concomitant GNAS and KRAS mutations were found in 18/52 (35%) cases. Most GNAS mutations were in codon 201 (R201C and R201H); one Q227L mutation, not previously described in IPMNs, was also detected; KRAS mutations were in codon 12 in all but five cases, which were one in codon 14 (V14I) (Figure 4), one in

Figure 3. Concomitant IPMN and ITPN sharing a common GNAS mutation. Patient 130fp presented two different neoplastic lesions, an intestinal-type IPMN and an ITPN coexisting in pancreatic head. The two phenotypically different lesions showed a common GNAS R201H mutation; the ITPN component presented a NRAS Q61L mutation; representative H&E images of the lesions are shown (original magnifications = ×20). On the right of each sample is a representation of the reads aligned to the reference genome, as provided by the Integrative Genomics Viewer software (IGV v 2.1, Broad Institute) for the hotspot mutations in the GNAS and NRAS genes.

The prevalence of mutations in the other genes sequenced was lower. Five (10%) of the 52 lesions harboured a TP53 mutation and three (6%) a BRAF mutation; mutations in CTNNB1, IDH1, STK11 and PTK were each found in two tumours (2/52, 4%); ATM, CDH1, CDKN2A, FGFR3, NRAS, SMAD4 and SRC gene mutations were each found in only one of the 52 cases (1/52, 2%). All these genes were mutated in association with GNAS and/or KRAS mutations, with the exception of two IPMNs, one that only had a FGFR3 mutation and another that only had a TP53 mutation (see supplementary material, Table S2).

Validation of mutations in six genes and screen for RNF43 mutations using an AmpliSeq custom panel

Forty-two of the 52 DNA samples (33 FF, nine FFPE) were re-analysed, using a custom gene panel to confirm the mutations in six genes (BRAF, CDKN2A, GNAS, KRAS, SMAD4 and TP53) and to evaluate the role of RNF43, a gene that was not included in the first gene panel. An adequate library for subsequent sequencing was obtained for all samples. Mean 100× coverage of 100% with a mean read length of 175 bp was achieved in the 33 FF samples, and mean 100× coverage of 99.24% with a mean read length of 150 bp was achieved in the nine FFPE samples.

All the mutations identified in the first analysis were confirmed, with negligible variations of allelic frequencies (see supplementary material, Table S3); an additional mutation in CDKN2A (A148T) was detected due to the longer region of gene covered by the custom panel. Mutations in RNF43 gene were detected in six of the 42 samples (14%) and included: one deletion (M18Pfs*31) in exon 2; two insertions (R117Qfs*8 and E258*) in exons 3 and 7, respectively; two missense variants (N179K) in exons 5 and 9 (S321I); and one nonsense (R371*) in exon 9.

Validation of mutations in five genes, using Sanger sequencing and immunohistochemistry

Mutations in KRAS (exons 2 and 3), GNAS (exons 8 and 9), BRAF (exon 15) and TP53 (exons 5, 6, 7 and 8), detected by deep sequencing, were all confirmed by Sanger sequencing. We used p53 and β-catenin nuclear immunolabelling as a surrogate validation for TP53 and CTNNB1 mutational status. For TP53, cases 114, 939p...
and 138fp showed abnormal p53 nuclear accumulation of the mutated protein; cases 106 and 108, respectively, harbouring the N247_R249del frame-shift deletion and the homozygous R306X mutation, had no immunolabelling (Figure 5). Two CTNNB1-mutated cases had nuclear immunopositivity for β-catenin.

Evaluation of CDKN2A/P16 and SMAD4 dysregulation using immunohistochemistry

Immunohistochemistry was used as a surrogate test to assess the involvement of CDKN2A/P16 and SMAD4 genes [7,24,25]. In fact, protein expression may more accurately reflect gene status, as both genes are mainly inactivated by homozygous deletion, and CDKN2A/P16 also by promoter methylation.

Material was available for 36 cases: 34 IPMNs (23 intestinal-type, five gastric-type, three pancreaticobiliary and three oncocytic-type) and two ITPNs. In 17 IPMNs the non-invasive lesion coexisted with invasive carcinoma, for a total of 53 lesions analysed (ie 34 IPMNs, two ITPNs and 17 invasive carcinomas).

In normal pancreatic parenchyma, p16 was expressed in Langerhans’ islets and in random acinar and duct cells (Figure 6). P16 loss was observed in 19/53 (36%) lesions, distributed as follows: 0/1 (0%) LG; 3/13 (23%) IG; 7/22 (31%) HG; and 9/17 (53%) invasive carcinomas. Most p16-loss cases (9/10) were intestinal-type IPMNs. Only one of the two CDKN2A/P16-mutated IPMNs was available for immunophenotyping, and it lacked p16 expression.

Normal pancreatic parenchyma showed strong nuclear and cytoplasmic Smad4 expression in all cell types, including Langerhans’ islets, acinar cells, stromal cells and duct cells (Figure 6). Only one intestinal-type IPMN showed loss of Smad4 expression. Four IPMN-associated invasive carcinomas were Smad4-negative, with the coexisting Smad4-positive non-invasive component. Case 137fp, harbouring a F253C SMAD4 mutation, expressed Smad4. Thus, 5/17 (29%) invasive carcinomas had Smad4 alterations.

The two ITPNs showed strong immunoreactions for both p16 and Smad4.

Mutation prevalence according to histological subtype

Among IPMNs, at least one somatic mutation was observed in 46/48 (96%) cases, while 29 neoplasms (60%) had multiple gene alterations (Table 3; see also supplementary material, Table S2). GNAS and/or KRAS mutations were found in 44/48 (92%) IPMNs: GNAS was mutated in 38/48 (79%) cases, KRAS in 24/48 (50%), and these mutations coexisted in 18/48 (37.5%) cases.

All six gastric-type IPMNs harboured a GNAS mutation and five of these cases also had a KRAS mutation (Table 3). Among intestinal type IPMNs, most
Figure 5. TP53 mutational status corresponds to p53 protein accumulation. (A) Case 939 showed a heterogeneous pattern of staining, which is consistent with TP53 mutational status (21% of mutated alleles, I195N). (B) Case 108, with no evident p53 labelling, corresponds to a homozygous stop mutation (83% of mutated alleles, R306*). For each sample, a representative p53 immunohistochemical image (original magnification = ×20) and a representation of the reads aligned to the reference genome, as provided by the Integrative Genomics Viewer software (IGV v 2.1, Broad Institute), are presented.

Table 3. Mutational profiling of the 52 intraductal pancreatic neoplasms according to pathological data

| Genes  | Total (n = 52) | Gastric (n = 6) | Intestinal (n = 36) | Pancreaticobiliary (n = 3) | Oncocytic (n = 4) | LG (n = 17) | IG (n = 28) | HG (n = 20) | Carcinoma (n = 32) |

LG, low-grade dysplasia; IG, intermediate-grade dysplasia; HG, high-grade dysplasia. ITPN, intraductal tubulopapillary neoplasm.

TP53 and BRAF alterations were each observed in three of the 36 (8%) intestinal-type IPMNs and in none of the gastric IPMNs. Among the less-represented IPMN subtypes (pancreaticobiliary, n = 3; oncocytic, n = 3), GNAS and KRAS variants were present in the pancreaticobiliary and oncocytic IPMNs (one of three GNAS, and/or KRAS).
and two of three KRAS). Notably, TP53 was mutated only in the pancreaticobiliary-type IPMNs (two of three). RNF43 mutations were detected in four (12%) of 32 intestinal-type and one of two pancreaticobiliary-type IPMNs, and were always associated with GNAS and/or KRAS mutations. None of the gastric, oncocytic or ITPN types had p16 mutations.

The only mutations detected in the four ITPNs were detected in case 130fp, where the coexisting IPMN and ITPN lesions shared the same GNAS R201H mutation; this ITPN also had an additional NRAS Q61L mutation (Figure 3; see also supplementary material, Table S2).

### Mutation prevalence according to tumour grade

Low- or intermediate-grade dysplastic samples were characterized by recurrent mutations in GNAS (90%) and KRAS (65%), while the prevalence of these mutations was significantly lower in high-grade/invasive carcinoma samples (66% of the high-grade lesions harboured a GNAS and 34% a KRAS mutation; \( p = 0.0001 \) and \( p = 0.046 \), respectively) (Table 3). We had significantly more intestinal-type IPMNs than in the series by Wu et al [10], and this was likely a factor in the lower prevalence of mutant KRAS in the IPMNs with high-grade dysplasia (see supplementary material, Table S2). Notably, TP53 and BRAF mutations were found in high-grade lesions (15% and 9%, respectively) but not in any of the low- or intermediate-grade lesions.

### Mutations in matched non-invasive and invasive tumours

Three cases (128fp, 129fp and 138fp) with matched non-invasive and invasive components had similar mutational profiles (Table 2, Figure 2). Seven mutations observed in the GNAS, KRAS, BRAF, KRAS and STK11 genes were shared between the pre-invasive and invasive lesions; three point mutations in CDKN2A, SMAD4 and PTEN were observed in only one of the matched lesions.

### NGS can identify IPMN specific mutations in cystic fluid

DNAs from cystic fluids were available for 10 intestinal-type IPMNs, and were deep sequenced with the 50-gene AmpliSeq Cancer Panel. An adequate library was obtained in seven cyst fluids and sequencing detected 10 of the 13 mutations present in the matched IPMNs, including six of seven GNAS mutations, three of three KRAS mutations and one of two TP53 mutations.

### Discussion

Intraductal papillary mucinous neoplasms are important precursors to invasive pancreatic cancer and represent an opportunity for the detection and treatment of pancreatic neoplasia before an invasive carcinoma develops [2,26–28]. While the phenotypic classification of IPMNs is well established, the molecular drivers...
of this precursor lesion have yet to be fully characterized [4,12,17,29]. In this study, we explored the mutational status of 51 cancer-related genes in 52 intraductal lesions, including 48 IPMNs and four ITPNs, and tested the diagnostic performance of the test on 10 cystic fluid samples.

The 48 IPMNs harboured frequent somatic mutations in *GNAS* and *K Ras*, and at least one of the two genes was mutated in 44/48 (92%) of the IPMNs. *GNAS* mutations were identified in 79% of tumours and most of them involved codon 201. *K Ras* was mutated in 50% of IPMNs, and mutations were located in codons 12, 14, 22 and 61. Our literature review finds that *K Ras* codon 14 mutations have never been reported for colorectal or pancreatic cancer. Although *K Ras* codon 14 mutations are rare, they are considered as drivers in nature [30,31]. The high prevalence of *GNAS* and *K Ras* mutations found in our series is similar to that of previous studies, and suggests that these genes may be ideal targets for early detection efforts [11,32].

*RNF43* was the gene with the third most frequent intragenic mutation detected by our sequencing analysis. These *RNF43* mutations were always associated with *GNAS* and/or *K Ras* mutations. Five of the six mutations detected are newly described, as only one had been previously reported for IPMN [11,32]. Our series adds to the limited literature regarding the prevalence and distribution of *RNF43* in this class of tumours, as only eight IPMNs have been evaluated for *RNF43* mutations in the literature [10].

For other genes, mutations were detected in a small percentage (< 5%) of samples in *CDKN2A, C TNBB1, IDH1, STK11* and *PTEN* (each one in two of the 52 tumours) and *ATM, CDH1, FGFR3, NRAS, SMAD4* and *SRC* (each one in one of the 52 neoplasms). These genes were mutated in association with *GNAS* and/or *K Ras* mutations, with the exception of two IPMNs, one IPMN that only had a *FGFR3* mutation and another that only had a *TP53* mutation. Prior studies have reported *STK11* mutations in a similar percentage of IPMNs (9%) [8]. Prior studies have found *ATM* and *CDH1* somatic mutations in a small percentage of pancreatic ductal adenocarcinomas, but these mutations have not yet been reported in IPMNs [33,34]. Somatic mutations in *IDH1, PTEN, FGFR3, NRAS* and *SRC* have not been reported in IPMNs or in pancreatic ductal adenocarcinomas [33,34]. *CTNNB1* mutations are characteristic of pancreatic solid and pseudopapillary tumours, but nuclear expression of β-catenin has been described in some IPMNs [17]. The mutations we found in *IDH1, NRAS* and *CTNNB1* arose in known hotspots for these genes. Although *PTEN* mutations have not been previously reported in IPMNs or ITPNs [12], loss of *PTEN* expression in IPMNs has been reported [35], and mutations in *PIK3CA*, another gene in this pathway, also occur in a small percentage of cases [5,16,35]. The pathogenetic role of *CDKN2A/P16* and *SMAD4* was further investigated by immunohistochemical analysis. Our results demonstrated that 36% of IPMNs show loss of p16 and 24% of IPMN-related invasive carcinomas loss of Smad4, which is in accordance with previous studies [4,7].

The different histological subtypes of IPMNs showed a partial overlap in the mutational spectrum as well as some differences. *G N A S* gene mutations were common in all types, consistent with previous reports [10,11,32,36]. *K Ras* mutations were more common in gastric-type compared to intestinal-type IPMNs (83% versus 39%, *p* = 0.07), as has been reported by Mohri et al [82% versus 27%] [4]. Other authors have reported that oncocytic-type IPMNs are less likely to have *K Ras* gene mutations than pancreaticobiliary type-IPMNs [17], while in our study all three pancreaticobiliary and two of three oncocytic cases harboured *K Ras* mutations.

Three of four ITPNs had no mutations in the 50-gene panel. The ITPN that coexisted with an IPMN had mutations in both *GNAS* and *NRAS*. The mutation observed in *GNAS* is of note, because Yamaguchi and colleagues [18] have recently reported that this gene was not mutated in a series of 14 ITPNs. Previous reports found activating *PIK3CA* mutations in three of 14 (21%) ITPNs [12,18]. Two different groups identified *PIK3CA* mutations in 11% (4/36) and 9% (2/21) of IPMNs, respectively [5,16]; it is noteworthy that the missense hot-spot mutation H1047R in exon 20 was found in four of six invasive cancers. In our series, *PIK3CA* mutations were absent in both ITPNs and IPMNs; given the good quality of sequences we obtained, this discrepancy is possibly due to the small number of cases analysed by each of the three studies. Although we only analysed four ITPN cases, the absence of *K Ras* and *BRAF* mutations in ITPN supports the hypothesis of a distinct molecular profile and possibly an independent origin for ITPN lesions. *TP53* and *BRAF* mutations were only found in high-grade lesions (15% and 9%, respectively), suggesting that these mutations could be a potential diagnostic marker for high-grade dysplasia.

Recent guidelines emphasize conservative management of patients with IPMNs unless there are stigmata of cancer [37], particularly for elderly patients who often have comorbid conditions that increase surgical risk. Because pancreatic imaging does not provide sufficient information about the characteristics of pancreatic cysts, a fine needle is used for further evaluation, but current tests do not provide sufficient diagnostic information. Therefore, the identification of novel diagnostic approaches based on genetic analyses of cyst fluid aspirated at the time of endoscopic ultrasound is particularly appealing. In the present study, we demonstrate that targeted next-generation sequencing is feasible with cystic fluid samples, and can provide information about the genetic profile of these lesions. Notably, cyst fluid analysis identified only 10 of the 13 somatic mutations found in the corresponding IPMNs. We suspect that this was because of a low concentration of mutations in the cyst fluid, below the limit of detection of our assay, and this could be related to how the cyst fluids were sampled. Further study is needed to evaluate the concentration of mutations in IPMN cyst fluids. There are
other approaches that can be employed to increase the limit of detection of next-generation sequencing, such as BEAMing or Safe-Seqs analysis [11,38].

The prevalence of KRAS mutations in our series (50%) of IPMNs is lower than that observed by Wu and colleagues [11], who reported 79% prevalence of KRAS mutations in IPMNs. This difference is reflected in differences in the prevalence of the histological subtypes of IPMNs in the two series: Wu et al. studied 48 IPMNs, the majority of which were gastric-type (27 cases), and included 10 intestinal-type, five pancreaticobiliary-type and six undetermined. Our series included six gastric-type and 36 intestinal-type IPMNs (see Table 3). For gastric-type IPMNs, KRAS mutations were found in 25/27 (93%) cases of Wu et al. and in 5/6 (83%) of our series; for intestinal-type IPMNs, they found mutations in 4/10 (40%) of cases, whereas we found mutations in 14/36 (39%) of cases.

In conclusion, gastric and intestinal IPMNs commonly harbour GNAS and KRAS gene mutations that likely precede mutations in other genes that are less common in IPMNs and, when found, are generally more common in higher-grade lesions. Moreover, our data also confirm the suggestion that ITPN appears to be a pancreatic intraductal disease different from IPMN [12,18]. TP53 gene mutations have only been found in higher-grade lesions, suggesting that these mutations could be a specific marker for high-grade dysplasia or invasive cancer. Next-generation sequencing of cystic fluid samples can identify the majority of mutations arising in IPMNs, potentially improving the diagnostic and prognostic stratification of IPMNs.

Acknowledgements

We thank Dr Samantha Bersani for her valuable help in performing immunohistochemistry. The study was supported by the Italian Cancer Genome Project (Grant No. FIRB RBAP10AH1B), Associazione Italiana Ricerca Cancro (AIRC; Grant Nos 12182 and 6421), Fondazione Italiana Malattie Pancreas – Ministero Salute (Grant No. CUP_J33G13000210001), the National Institutes of Health (Grant No. CA62924), Susan Wojcicki and Dennis Troper, and the Michael Rolfe Foundation. The funding agencies had no role in the collection, analysis and interpretation of data or in the writing of the manuscript.

Author contributions

AS, MF, RHH and AMaitra conceived the study; EA and MdM designed the validation experiment; MG supervised the validation experiment; RTL coordinated patients and sample data management and supervised ethical protocols; GM, RS and CB collected materials and clinical data; BR, MF, PCapelli, GZ and AS analysed histopathological data; MF, BR and PCastelli microdissected samples; EA, MdM, JY, DA and YA carried out deep sequencing and raw data analysis; AMafficini and JY performed bioinformatic analysis; MF, PCastelli and GZ analysed immunohistochemistry; EA, AMafficini, MF and MdM drafted the manuscript; AMafficini, MG, RHH, AMaitra and RTL revised the manuscript; and AS finalized the paper. All authors approved the submitted version.
