Abstract

Using the non-equilibrium quantum field theory, photon production from the coherently oscillating axion field in a flat Robertson-Walker cosmology is re-examined. First neglecting the Debye screening of the baryon plasma to photons, we find that the axions will dissipate into photons via spinodal instability in addition to parametric resonance. As a result of the pseudo-scalar nature of the axion-photon coupling, we observe a circular polarization asymmetry in the produced photons. However, these effects are suppressed to an insignificant level in the expanding universe. We then briefly discuss a systematic way of including the plasma effect which can further suppress the photon production. We note that the formalism of the problem can be applied to any pseudo-scalar field coupled to photon in a thermal background in a general curved spacetime.

I. INTRODUCTION

It is compelling that most of the matter in the universe is in a form of non-baryonic cold dark matter. If it exists, it would play an important role in the structure formation of the universe [1]. Axions, the pseudo-Goldstone bosons, are among the most promising candidates for the non-baryonic cold dark matter. They arise from the spontaneous breaking of a global $U(1)$ symmetry of Peccei and Quinn (PQ), which is introduced to solve the strong CP problem of QCD [2–4]. In the standard big-bang cosmology, after the spontaneous breakdown of the PQ symmetry, the expectation value of the axion field (i.e. the axionic condensate) takes some random value on the interval $[0, 2\pi]$ and, is approximately constant over length scales which are smaller than the horizon size [5]. If inflation occurs either after or during the PQ symmetry breaking, then the expectation value can be nearly constant throughout the entire universe [6]. At high temperatures above the $\Lambda_{\text{QCD}}$ scale, the axion is massless; however, at low temperatures, the axion develops a mass due to QCD instanton effects [7]. Once the axion mass becomes greater than the universe expansion rate, the expectation value of the axion field begins to oscillate coherently around the minimum of its effective potential that is near the origin. The oscillating axion field then dissipates mainly due to the universe expansion as well as particle production [2,3].

In the original papers [2], simple estimates of the thermal dissipation of the homogeneous axionic condensate were given. They considered instabilities arising from the parametric amplification of quantum fluctuations that could pump the energy of the homogeneous axionic condensate into its quantum fluctuations via self couplings, as well as into quantum fluctuating photon modes via a coupling of the axion to electromagnetism due to the color anomaly of the PQ symmetry. This dissipational dynamics via quantum particle production exhibits the feature of unstable bands, and an exponential growth of the quantum fluctuating modes that are characteristics of parametric resonance. The growth of the modes in the unstable bands translates into profuse particle production. A given unstable mode will grow as long as it lies within the unstable band. However, eventually it will be red-shifted out of the band as the universe expands, and then the instabilities of parametric resonance are shut off. In Ref. [2], it has been shown that for the PQ symmetry breaking scale $f_a > 10^{12}\text{GeV}$, because the axion is very weakly coupled, the time it takes to be red-shifted out of the unstable band is too short to build up an appreciable growth of the quantum fluctuating modes. Thus, all of these effects are insignificant. The condensate is effectively nondissipative and pressureless. It would survive in the expanding universe, and it behaves like cold dust at the present time. Interestingly, if $f_a \sim 10^{12}\text{GeV}$, it could constitute a major component of the dark matter of the universe.

Recently, the authors of Ref. [8] were motivated by the recent understanding of the important role of the spinodal instability and parametric resonance that provide the nonlinear and nonperturbative mechanisms in the quantum particle production driven by the large amplitude oscillations of the coherent field [9–13]. They re-examined the issue of the dissipation of the axion field resulting from the production of its quantum fluctuations. They confirmed that the presence of the parametric resonance would lead to an explosive growth of quantum fluctuations if the universe was Minkowskian. Taking account of the expansion of the universe, quantum fluctuations of the axion do not become significant. This result confirms the conventional wisdom.
In this paper, we will re-examine the damping dynamics of the axion arising from photon production in an expanding universe in the context of the non-equilibrium quantum field theory. The goal of this study is to present a detailed and systematic study of the above-mentioned problem using a fully non-equilibrium formalism \[9–13\]. We will derive the coupled nonperturbative equation for the axion field and the mode equations for the photon field in a flat Robertson-Walker spacetime within the nonperturbative Hartree approximation that is implemented to consistently take the back reaction effects into account. We then try to study both numerically and analytically how the nonperturbative effects of spinodal instability and parametric amplification of quantum fluctuations trigger photon production from the oscillations of the axion field. At this stage, it is worthwhile to mention that our approach can be generalized to any pseudo-scalar field coupled to the photon field in a more general curved spacetime. Since the pseudo-scalar nature of the coupling between the axion and the photon, the axion field affects the left- and right-handed circularly polarized photons differently. This leads to producing the two polarized photons in different amounts. This polarization asymmetry, if it survives, may have interesting effects on the polarization of the cosmic microwave background.

To consider the fermionic plasma effect on photon production, one must systematically obtain the non-equilibrium in-medium photon propagators and the off-equilibrium effective vertices between the axion and the photon by integrating out the fermionic field to deal with this problem \[12\]. In a plasma, the transverse photons are dynamically screened \[14\]. However, in the literatures \[4\], the arguments stated to include the fermionic plasma effect in support of their conclusions amount to adding by hand the electron plasma frequency into the propagating photon mode equations. This is problematic when we consider propagating photon modes in the presence of a thermal background. In fact, the consequence of the Abelian ward identities reveals that the transverse photons have the vanishing static magnetic mass in all orders of the perturbation theory \[14\]. This means that the in-medium transverse photon propagators must be nonlocal in nature, and cannot be approximated by the local propagator as suggested in Ref. \[2\] even in the low energy limit \[12\]. Besides, in a fermionic plasma, the effective coupling between the axion and the photon resulting from integrating out the fermionic thermal loop can be modified both at finite temperature as well as out of equilibrium \[12\]. Therefore, to fully consider the plasma effect, the non-equilibrium in-medium photon propagators as well as the off-equilibrium effective vertices play the essential roles. However, incorporating these non-equilibrium effects is a challenging task that lies beyond the scope of this paper, but certainly deserves to be taken up in the near future. In the following, we will totally ignore the fermionic plasma effect in order to focus on understanding whether the particle production due to spinodal instability as well as parametric amplification is effective or not in the cosmological context.

In Sec. \[I\] we introduce the axion physics and its coupling to the photon. An effective action of the axion-photon system in the expanding universe is derived. Sec. \[III\] is devoted to the formalism of the problem in terms of non-equilibrium quantum field theory. We obtain the equation of motion for the classical axion field and the photon mode equations. In Sec. \[V\] we present the numerical results. Sec. \[V\] is our conclusions.
II. EFFECTIVE ACTION OF AXION-PHOTON COUPLING IN EXPANDING UNIVERSE

The physics of axion and its implication to astrophysics and cosmology can be found in the review articles [3,15]. The axion does not couple directly to the photon. However, at tree level, the axion field $\phi$ has a coupling with the fermionic field $\psi$,

$$L_{\phi\psi} = g\phi\bar{\psi}\psi.$$  \hspace{1cm} (2.1)

Therefore, the axion can couple to the photon via a fermionic loop. As a consequence of the color anomaly of the PQ current, similar to the pion-photon system, the effective Lagrangian density for the axion-photon coupling is

$$L_{\phi A} = c\phi f_a \epsilon^{\alpha\beta\mu\nu} F_{\alpha\beta} F_{\mu\nu},$$ \hspace{1cm} (2.2)

where $F_{\mu\nu} = \partial_{\mu}A_{\nu} - \partial_{\nu}A_{\mu}$. In Eq. (2.2), the scale $f_a \equiv f_{PQ}/N$, where $f_{PQ}$ is the PQ symmetry breaking scale, and $N$ is the color anomaly of the PQ symmetry. The coupling constant $c = \alpha(E_{PQ}/N - 1.95)/(16\pi)$, where $E_{PQ}$ is the electromagnetic anomaly of the PQ symmetry, and $\alpha$ is the fine structure constant. Henceforth, we assume an axion incorporated into the simplest GUTs with $E_{PQ}/N = 8/3$, such that $c \simeq 1.04 \times 10^{-4}$ [16].

Now we write down the effective action for the axion-photon system in the expanding universe,

$$S = \int d^4x\sqrt{g}\left( L_{\phi} + L_{A} + \frac{1}{\sqrt{g}}L_{\phi A}\right),$$ \hspace{1cm} (2.3)

where $1/\sqrt{g}$ is added in front of $L_{\phi A}$, given by Eq. (2.2), because $\epsilon^{\alpha\beta\mu\nu}$ is a tensor density of weight $-1$ [17]. In the following, for simplicity, we will assume a flat Robertson-Walker metric

$$ds^2 = -g_{\mu\nu}dx^\mu dx^\nu = dt^2 - a^2(t)d\vec{x}^2,$$ \hspace{1cm} (2.4)

where the signature is $(-+++)$, and $a(t)$ is the cosmic scale factor. In Eq. (2.3),

$$L_{\phi} = -\frac{1}{2}g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi - V(\phi, T),$$ \hspace{1cm} (2.5)

$$L_{A} = -\frac{1}{4}g^{\alpha\mu}g^{\beta\nu}F_{\alpha\beta}F_{\mu\nu},$$ \hspace{1cm} (2.6)

where the axion potential has a temperature-dependent mass term due to QCD instanton effects, being of the form [8]

$$V(\phi, T) = m_a^2(T)f_a^2 \left( 1 - \cos\frac{\phi}{f_a}\right),$$ \hspace{1cm} (2.7)

$$m_a(T) \simeq 0.1m_{a0}\left(\frac{\Lambda_{QCD}}{T}\right)^{3.7},$$ \hspace{1cm} (2.8)

where $m_{a0}$ is the zero-temperature axion mass, satisfying $m_{a0}f_a \simeq 6.2 \times 10^{-3}$GeV$^2$. Also, we use $\Lambda_{QCD} \simeq 200$MeV.
It is well known that the minimal coupling of photons to the metric background is conformally invariant \[18\]. As such, in the conformally flat metric \( \eta \), it is convenient to work with the conformal time, \( d\eta = a^{-1}(t)dt \). Hence, defining \( \phi = \chi/a \), the action (2.3) becomes

\[
S = \int d\eta \, d^3\vec{x} \, L = \int d\eta \, d^3\vec{x} \left[ \frac{1}{2} \left( \frac{\partial \chi}{\partial \eta} \right)^2 - \frac{1}{2a} \frac{d^2a}{d\eta^2} \chi^2 - a^4 V(\frac{\chi}{a}, T) - \frac{1}{4} \eta^{\alpha\mu} \eta^{\beta\nu} F_{\alpha\beta} F_{\mu\nu} + \frac{c}{a^2} \epsilon^{\alpha\beta\mu\nu} F_{\alpha\beta} F_{\mu\nu} \right],
\]

where \( \eta^{\alpha\mu} \) is the Minkowski metric. In terms of the conformal time, the effective action now has analogy with the effective action in Minkowski spacetime with the time dependent mass term and interactions.

III. EQUATIONS OF MOTION

The non-equilibrium effective Lagrangian in the closed time path formalism \[9–11\] is given by

\[
\mathcal{L}_{\text{neq}} = \mathcal{L} \left[ \chi^+, A^+_\mu \right] - \mathcal{L} \left[ \chi^-, A^-_\mu \right],
\]

where + (-) denotes the forward (backward) time branches. We then decompose \( \chi^\pm \) into the axionic mean field and the associated quantum fluctuating fields:

\[
\chi^\pm (\vec{x}, \eta) = \varphi(\eta) + \psi^\pm (\vec{x}, \eta),
\]

with the tadpole conditions,

\[
\langle \psi^\pm (\vec{x}, \eta) \rangle = 0.
\]

We will implement the tadpole conditions to all orders in the corresponding expansion to obtain the non-equilibrium equations of motion.

To take account of the back reaction effects on the dynamics of the axion field from quantum fluctuating photon modes, we adopt the following Hartree factorization which is implemented for both \( \pm \) components \[9–11\]:

\[
\psi F \tilde{F} \to \psi \langle F \tilde{F} \rangle.
\]

As seen later, the expectation value can be determined self-consistently. It must be noted that there is no a priori justification for such a factorization. However, this approximation provides a nonperturbative framework that allows us to treat photon fluctuations self-consistently \[11\]. On the contrary, we will ignore the quantum fluctuations of the axion, which can be produced via self-couplings, as the study of Ref. \[8\] has shown that these effects are insignificant.

With Eq. (3.2), we first expand the non-equilibrium Lagrangian density (3.1) in powers of \( \psi \) and keep the term up to linear \( \psi \) to ignore its quantum fluctuation effects. Together with Eq. (3.4), the Hartree-factorized Lagrangian then becomes
\[ L \left[ \phi(\eta) + \psi^+, A^+_{\mu} \right] - L \left[ \phi(\eta) + \psi^-, A^-_{\mu} \right] = \left\{ -U(\eta)\psi^+ - \frac{1}{4} F^{\mu\nu}_\eta \tilde{F}^{\mu\nu}_\eta + \frac{c}{a f_a} \phi(\eta) F^{\mu\nu}_\eta \tilde{F}^{\mu\nu}_\eta \right\} \] 

where

\[ U(\eta) = \phi(\eta) - \frac{\dot{a}(\eta)}{a(\eta)} \phi(\eta) + a^2(\eta) m_a^2(T) f_a \sin \left[ \frac{\phi(\eta)}{a(\eta)f_a} \right]. \] 

The dot means the time derivative with respect to the conformal time.

With the tadpole conditions (3.3), we obtain the following equation of motion for the axionic mean field given by

\[ \ddot{\theta}(\eta) + 2 \frac{\dot{a}(\eta)}{a(\eta)} \dot{\theta}(\eta) + a^2(\eta) m_a^2(T) \sin \theta(\eta) - \frac{1}{a^2(\eta)} \left( \frac{c}{f_a^2} \right) \langle F \tilde{F} \rangle(\eta) = 0, \] 

where we define the dimensionless field, \( \theta(\eta) = \phi(\eta)/(a(\eta) f_a) \).

Within the Hartree approximation, the photon production processes do not involve photons in the intermediate states \([11,13]\). To avoid the gauge ambiguities, we will work in the coulomb gauge and concentrate only on physical transverse gauge field, \( \tilde{A}_T(\vec{x}, \eta) \) \([11,13]\). Then, the Heisenberg field equation for \( \tilde{A}_T(\vec{x}, \eta) \) can be read off from the quadratic part of the Lagrangian in the form

\[ \frac{d^2}{d\eta^2} \tilde{A}_T(\vec{x}, \eta) - \tilde{\nabla}^2 \tilde{A}_T(\vec{x}, \eta) + 4c \dot{\theta}(\eta) \tilde{\nabla} \times \tilde{A}_T(\vec{x}, \eta) = 0. \] 

It is more convenient to decompose the field \( \tilde{A}_T(\vec{x}, \eta) \) into the Fourier mode functions \( V_{\lambda k}(\eta) \) in terms of circularly polarized states,

\[ \tilde{A}_T(\vec{x}, \eta) = \int \frac{d^3k}{\sqrt{2(2\pi)^3}} \tilde{A}_T(\vec{k}, \eta) \] 

\[ = \int \frac{d^3k}{\sqrt{2(2\pi)^3}} \left\{ b_{+\vec{k}} V_{1k}(\eta) e^{i\vec{k} \cdot \vec{x}} + b_{-\vec{k}} V_{2\vec{k}}(\eta) e^{-i\vec{k} \cdot \vec{x}} \right\} e^{i\vec{k} \cdot \vec{x}} + \text{h.c.}, \] 

where \( b_{\pm\vec{k}} \) are destruction operators, and \( e_{\pm\vec{k}} \) are circular polarization unit vectors defined in Ref. \([11]\). Then the mode equations are

\[ \frac{d^2V_{1k}(\eta)}{d\eta^2} + k^2 V_{1k}(\eta) - 4k c \dot{\theta}(\eta) V_{1k}(\eta) = 0, \] 

\[ \frac{d^2V_{2k}(\eta)}{d\eta^2} + k^2 V_{2k}(\eta) + 4k c \dot{\theta}(\eta) V_{2k}(\eta) = 0, \] 

with the expectation values given by \([11]\)

\[ \langle F \tilde{F} \rangle(\eta) = \frac{1}{\pi^2} \int k^2 dk \cosh \left[ \frac{k}{2T_\ast} \right] \frac{d}{d\eta} \left( |V_{1k}(\eta)|^2 - |V_{2k}(\eta)|^2 \right), \]
where we have assumed that at initial time $\eta_i$, the photons are in local equilibrium at the initial temperature $T_i$. Clearly, the photon mode equations (3.10) are decoupled in terms of the circular polarization mode functions. The axion field acts as the time dependent mass term that triggers photon production. The effective mass terms have opposite signs for the two polarizations due to the pseudo-scalar nature of the axion-photon coupling. This will lead to producing the different polarized photons in different amounts, resulting in a polarization asymmetry in photon emission. The expectation value of the number operator for the asymptotic photons with momentum $\vec{k}$ is given by

\[
\langle N_k(\eta) \rangle = \frac{1}{2k} \left[ \hat{A}_T(\vec{k}, \eta) \cdot \hat{A}_T(-\vec{k}, \eta) + k^2 \hat{A}_T(\vec{k}, \eta) \cdot \hat{A}_T(-\vec{k}, \eta) \right] - 1
\]

\[
= \frac{1}{4k^2} \coth \left[ \frac{k}{2T_i} \right] \left[ |\tilde{V}_{1k}(\eta)|^2 + k^2 |V_{1k}(\eta)|^2 \right] - \frac{1}{2} + \frac{1}{4k^2} \coth \left[ \frac{k}{2T_i} \right] \left[ |\tilde{V}_{2k}(\eta)|^2 + k^2 |V_{2k}(\eta)|^2 \right] - \frac{1}{2}
\]

\[
= N_+(k, \eta) + N_-(k, \eta),
\]

(3.12)

which is the number of photons with momentum $\vec{k}$ per unit comoving volume.

**IV. NUMERICAL RESULTS**

In this section, we will compute the photon production from the axionic condensate with $f_a = 10^{12}\text{GeV}$, which has a zero-temperature mass $m_{a0} \approx 6.2 \times 10^{-6}\text{eV}$. As we will show below, the photon production takes place mainly during the radiation-dominated epoch. So, we simply assume a radiation-dominated universe.

At temperature $T$, the Hubble parameter is

\[
H \equiv \left( \frac{\dot{a}}{a} \right)^2 = \frac{5}{3} g^2(T) \frac{T^2}{m_{pl}},
\]

(4.1)

where $g(T)$ is the number of effective degrees of freedom at temperature $T$, $m_{pl}$ is the Planck scale, and the cosmic scale factor is

\[
a(\eta) = \frac{\eta}{\eta_1},
\]

(4.2)

where $\eta_1$ is the time when the axion field starts to oscillate, defined by a temperature $T_1$ such that $3H(T_1) = m_a(T_1)$. As such, $\eta_1^{-1} = m_a(T_1)/3$. For $f_a = 10^{12}\text{GeV}$, from Eqs. (2.8) and (4.1) we find $T_1 \approx 0.9\text{GeV}$ and $g(T_1) \approx 60$.

Changing the variable $\eta$ into $a$, the equations of motion (3.7) and (3.10) become

\[
\frac{d^2 \theta}{da^2} + \frac{2}{a} \frac{d \theta}{da} + 9a^2 \frac{m_a^2(T)}{m_a^2(T_1)} \sin \theta - \frac{9c}{m_a^2(T_1)a^2 f_a^2} \langle F^2 \rangle = 0, \tag{4.3}
\]

\[
\frac{d^2 V_{1\xi}}{da^2} + \xi^2 V_{1\xi} - 4\xi c \frac{d \theta}{da} V_{1\xi} = 0,
\]

\[
\frac{d^2 V_{2\xi}}{da^2} + \xi^2 V_{2\xi} + 4\xi c \frac{d \theta}{da} V_{2\xi} = 0, \tag{4.4}
\]
where \( \xi = k \eta \) and

\[
\frac{m_a^2(T)}{m_a^2(T_1)} = \begin{cases} \left( \frac{T}{T_1} \right)^{7.4} = a^{7.4} \left[ \frac{g(T)}{g(T_1)} \right]^{7.4} & T >> \Lambda_{QCD}, \\ 10^2 \left( \frac{T}{\Lambda_{QCD}} \right)^{7.4} & T << \Lambda_{QCD}. \end{cases}
\] (4.5)

Note that \( g(T) \) does not change significantly from \( T_1 \) to \( \Lambda_{QCD} \). Henceforth, we approximate \( g(T) \approx g(T_1) \approx 60 \), where \( T_1 = 0.9 \text{ GeV} \). It is worth to point out that the mode equations (4.4) have unstable modes via the spinodal instability for sufficiently low-momentum modes with \( \xi < 4c|d\theta/da| \), where the effective mass becomes negative.

To solve Eqs. (4.3) and (4.4), we have to specify the initial conditions for the axion and photon fields. The amplitude of the axion field is frozen for \( \eta << \eta_1 \), i.e.,

\[
\theta = 1, \quad \frac{d\theta}{da} = 0, \quad \text{as} \quad a = a_i << 1.
\] (4.6)

For the photon mode functions, we propose

\[
V_1 \xi = V_2 \xi = 1, \quad \frac{dV_1 \xi}{da} = \frac{dV_2 \xi}{da} = -i \xi, \quad \text{as} \quad a = a_i << 1.
\] (4.7)

These initial conditions are physically plausible and simple enough for us to investigate a quantitative description of the dynamics. To evaluate the \( \langle F \tilde{F} \rangle \) in Eq. (3.11) and the photon number operator in Eq. (3.12), we approximate the bose enhancement factor by

\[
\coth \left[ \frac{k}{2T_i} \right] = \coth \left[ \frac{\xi}{2\Gamma} \right] \simeq \frac{2\Gamma}{\xi},
\] (4.8)

where \( \Gamma \equiv \eta_1 T_i \geq \eta_1 T_1 \simeq 10^{18}, \) and we are interested in \( \xi < 100 \).

In Fig. 1, we plot the temporal evolution of the axion field and its time derivative by choosing \( a_i = 0.01 \) that corresponds to \( T_i = 100 T_1 \). Due to the expansion of the universe, the field amplitude decreases with time. However, the rate of change of the amplitude increases with time. To understand this, we redefine \( \tilde{\theta} \equiv \theta/a \) in Eq. (4.3). The \( \langle F \tilde{F} \rangle \) term can be neglected, being extremely small as shown in Fig. 2, where we have evaluated the last term of Eq. (4.3) denoted by \( \Sigma(a) \). Then, the equation of motion for \( \tilde{\theta} \) when \( \theta << 1 \) is given by

\[
\frac{d^2 \tilde{\theta}}{da^2} + 9a^2 \frac{m_a^2(T)}{m_a^2(T_1)} \tilde{\theta} = 0.
\] (4.9)

From Eq. (4.3), the solutions for \( \tilde{\theta} \) are Bessel functions. For \( T >> \Lambda_{QCD} \), asymptotically \( \tilde{\theta} \propto \cos(0.53 a^{0.7})/a^{2.35} \). For \( T << \Lambda_{QCD} \), \( \tilde{\theta} \propto \cos(3917 a^2)/a^{0.5} \). The latter shows that the axions behave like non-relativistic matter.

For the photon production, we calculate the spectral photon number density \( N(\xi, a) \), equal to \( \langle N_k(\eta) \rangle \) in Eq. (3.12). It is convenient to define a ratio,

\[
n(\xi, a) \equiv \frac{N(\xi, a) - N(\xi, a_i)}{N(\xi, a_i)},
\] (4.10)

which is the excess photons above the thermal background. Three snapshots of the ratio at \( a = 0.75, 1.5, \) and 3 are shown in Fig. 3. It is interesting to see that the production
duration of each non-zero mode is short, and higher-momentum modes are produced at later times. This in fact demonstrates a brief exponential growth of the unstable mode due to the parametric resonance instability, which is shut-off when the unstable mode has been red-shifted out of the unstable band. As a consequence, the photon production is limited with an excess photon ratio typically at a level of $10^{-7}$. As we have mentioned above, the spinodal instability happens for low-momentum photon modes. We demonstrate this numerically in Fig. 4, where we have chosen $\xi < 0.004$ that lie within the spinoidal region where $\xi < 4c|d\theta/da|$. The production ratio is also at a level of $10^{-7}$, but it is apparent that these low-momentum modes are produced during the first oscillating cycle of the axion field.

The ratio in Fig. 3 can be actually estimated as follows. First, let us find out the approximate form for $d\theta/da$ from Eq. (4.9) and Fig. 1, which is given by

$$\frac{d\theta}{da} \simeq 3.6 a^{1.35} \cos(0.53 a^{5.7}) \quad \text{for} \quad a_i << a < 8.4,$$

(4.11)

where $a = 8.4$ is the scale factor when $T = \Lambda_{QCD}$. At instant $a$, $d\theta/da$ is oscillating with an effective frequency $\omega = 0.53 a^{4.7}$. Inserting the approximate form (4.11) with $\omega$ treated as a constant into the mode equation of $V_{1\xi}$ in Eq. (4.4), and changing variable to $z = \omega a/2$, we have

$$\frac{d^2 V_{1\xi}}{dz^2} + \frac{4\xi^2}{\omega^2} V_{1\xi} - 58.1 c \frac{\xi}{\omega^2} a^{1.35} \cos(2z)V_{1\xi} = 0.$$

(4.12)

This is the standard Mathieu equations [19]. The widest and most important instability is the first parametric resonance that occurs at $\xi = \omega/2$ with a narrow bandwidth $\delta \simeq 14.5 c a^{1.35}/\omega$. But actually $\omega$ is changing with time. As such, the unstable mode will grow exponentially only during a brief period roughly given by

$$\Delta z \simeq \frac{\omega \delta}{\Delta a} \simeq \frac{\omega^2 \delta}{2 \Delta a}.$$

(4.13)

Consequently, this instability leads to the growth of the occupation numbers of the created photons by a growth factor,

$$e^{2\mu \Delta z} \simeq 1 + 2\mu \Delta z,$$

(4.14)

where the growth index $\mu \simeq \delta/2$. Hence the mode number density is increased by an amount approximately given by

$$2\mu \Delta z \simeq 42.6 c^2 a^{-1} \simeq 4.6 \times 10^{-7} a^{-1},$$

(4.15)

where $a$ is the scale factor when the mode $V_{1\xi}$ enters into the resonance band. This estimation is of the same order of magnitude as found in the numerical results. Interestingly, the $a^{-1}$ dependence of the mode production can also be seen in Fig. 3. Similar estimation can also be done for the mode function $V_{2\xi}$.

The polarization asymmetry in the produced photons is defined as

$$\Xi(\xi, a) = \frac{N_+(\xi, a) - N_-(\xi, a)}{N_+(\xi, a) + N_-(\xi, a)}.$$

(4.16)
We have input the mode solutions for $V_{1\xi}$ and $V_{2\xi}$ to Eq. (3.12) to calculate $\Xi(\xi, a)$ (4.16). A plot of the asymmetry versus the momentum at $a = 3$ is shown in Fig. 5. The numerical result shows that the asymmetry is fluctuating about zero as the photon momentum varies. The fluctuating amplitude is about $10^{-8}$ of the thermal background. Although the asymmetry averaged out over a wide range of momenta is nearly zero, at certain momenta the produced photons are about 10% circularly polarized. However, subsequently this polarization asymmetry will be damped out by photon-electron scatterings in the plasma.

V. CONCLUSIONS

First we basically confirm that the photon production via parametric resonance is invalidated by the expansion of the universe. Besides, we find that in addition to parametric resonance, for long-wavelength photon modes, a new dissipative channel via spinodal instability is open. This open channel results in the long-wavelength fluctuations of the photon modes. Again, this production is suppressed in the expanding universe. We also observe the polarization asymmetry in the produced circularly polarized photons as a result of the pseudo-scalar nature of the coupling. However, it will be damped out effectively by the plasma. But it is very interesting to see whether it is possible to generate a circular polarization asymmetry in the production of photons from certain pseudo-scalar fields such that it may leave an imprint on the polarization of the cosmic microwave background. As to the plasma damping on photon production, we have pointed out the problem in the naive approximation that simply introduces the electron plasma frequency to the photon modes. We have thus proposed a dynamical and non-equilibrium treatment which should be a better approach to consider the plasma effects. The actual calculations are rather difficult, but they certainly deserve further studies.

ACKNOWLEDGMENTS

We would like to thank D. Boyanovsky and H. J. de Vega for their useful discussions. The work of D.S.L. (K.W.N.) was supported in part by the National Science Council, ROC under the Grant NSC89-2112-M-259-008-Y (NSC89-2112-M-001-001).

FIGURE CAPTIONS

Fig. 1. Time evolution of the axion mean field $\theta(a)$ and its time derivative $d\theta(a)/da$, where $a$ is the cosmic scale factor.

Fig. 2. Time evolution of $\langle F\tilde{F}\rangle$, plotted with the quantity $\Sigma(a)$ given by the last term of Eq. (4.3).

Fig. 3. Three snapshots of the spectral number density ratio $n(\xi,a)$, defined in Eq. (4.10), of the photons produced via parametric amplification at $a = 0.75, 1.5,$ and $3$. The dimensionless quantity $\xi = k\eta_1$, where $k$ is the photon momentum and $\eta_1$ is the conformal time when the axion field starts to oscillate.

Fig. 4. As in Fig. 3 but for low-momentum photons produced via spinodal instability.

Fig. 5. Circular polarization asymmetry $\Xi(\xi,a)$, defined in Eq. (4.16), of the photons at $a = 3$ for $0 < \xi < 40$.
