Occupationally induced stress, strain and peak loads as related to age

by Juhani Ilmarinen, PhD,1 Joseph Rutenfranz, MD, PhD 2

Because physical work capacity and neuromuscular coordination decrease with age, some safety margins for daily work have been suggested. According to the World Health Organization, eg, oxygen consumption (VO₂) should not exceed 40–50% of the maximum (VO₂max) during prolonged occupational work (3). No upper limits have been given for peak loads however. It has been suggested that peak loads of short duration can exceed 50% of the VO₂max if the intermittent work intensity has been low (1). Any effort exceeding the VO₂max and lasting more than 4 min causes exhaustion and should be avoided (4).

Occupations with heavy physical work and/or high peak loads have decreased but not totally disappeared. The relative aerobic strain has been reported to be independent of age in construction work (2) but, on the other hand, to increase systematically with age after the age of 50 a in nonmotorized mail delivery (18). In a study on bank fishing (20) it was suggested that this heavy work need not be unsuitable for older fishermen if an effective job rotation is organized (20).

Our purpose was to study the relationship between strain and age in different groups of workers classified according to their specific work content.
Material and methods

The subjects were 120 men aged 23—60 from the following six types of work: construction industry (N = 19), iron and steel industry (N = 23), chemical industry (N = 17), retail trade (department store, N = 14), sales employees in the chemical industry (N = 29), and government employees (research institute, N = 18). From each type the most typical jobs were selected. The 120 men were arranged into four groups (table 1) according to the specific work content. First the Ergonomic Job Description Questionnaire was used (22), and, after a cluster analysis (14), the subjects were classified into the following homogeneous groups: group 1: producing forces (N = 21); group 2: coordinating motor and sensory functions (N = 37); group 3: converting information into reaction (N = 21); and group 4: transforming input-information into output-information (N = 30) and producing information (N = 11) (total N = 41).

Within these groups the following three age groups were formed: < 35, 35—50 and > 50 a. (The number of subjects in each age group can be found in table 4.)

To assess the work stress, the VO$_2$ during work was measured. The gas samples were collected with a Kofranyi-Michaelis gas meter and analyzed for oxygen (Servomex) and carbon dioxide (Unor). Two typical steady or nonsteady state phases of work were selected for the measurements. The measurements were carried out with a sample of 40 subjects, mainly doing physical work in groups 1 and 2.

The duration of different stress levels of work was registered with the diary method (11). A diary was kept by the subjects who did government and sales work; otherwise trained observers were used. The activities of the whole workday were classified into different stress levels adjusted to multiples of basal metabolic rates (MET), eg, S (sitting) = 150, SP (standing position) = 300, 1 (activity with minimum intensity) = 500, 2 (activity with medium

| Work content                          | Age (a) | Height (cm) | Weight (kg) | Fata (%) | Maximal oxygen consumption b (ml/min × kg) | Maximal heart rate b (beats/min) |

- Predicted according to triceps and scapula skinfolds (12).
- Predicted (see the methods section).
To assess the relativestrain, we calculated the HRmean as the percentage of heart rate range (%HRR) and as the percentage of individual maximal heart rate (%HRmax). The heart rate range was defined as the difference between resting and maximal heart rate. Standard table values for resting and maximal heart rates adjusted for age were used, but, when lower resting and/or higher maximal values than standard values were recorded, they were used for the analysis.

The relative aerobic strain (RAS) was defined as \( \frac{V_{O2}}{V_{O2}^\text{max}} \) during work as the percentage of the individual \( V_{O2}^\text{max} \). To assess the \( V_{O2}^\text{max} \), a submaximal test on a magnetically braked ergometer was used (17). The work load was continually increased up to 85 % of the age-predicted HRmax. The \( V_{O2}^\text{max} \) was predicted (15) from \( W_{170} \).

The difference in the stress and strain variables between the three age groups were tested with the Kruskal-Wallis one-way analysis of variance. Otherwise linear regression was used. The significances were assessed with two-tailed tests.

The 95 % confidence curves for HRmean and RAS were calculated according to Armitage (5).

Results

The characteristics of the subjects, arranged into four homogeneous groups according to work content, are given in table 1. Group 1 (“producing forces”), which involved mainly heavy physical work, included the following jobs: bricklayer, carpenter, concrete reinforcement worker, and smelter. Group 2, “coordinating motor and sensory functions,” consisted of iron workers, switchmen, workers in machine shops, and butchers. Group 3, “converting information into reactions,” covered such jobs as crane operator, foreman, watchman, and sales clerk. Group 4, “producing information,” was a combination of office employees, government employees, research assistants, and scientists. No statistically significant differences in the physiological characteristics of these four groups were found (table 1).
Table 2. Oxygen consumption \(a\) \((\text{VO}_2)\) of different work contents.

| Work content                          | Producing forces | Coordinating motor and sensory functions | Converting information into reaction | Producing information | All groups |

\(a\) Based on double measurements of each group.

Maximal oxygen consumption

The predicted \(\text{VO}_2\)\(_{\text{max}}\) decreased with age in all four groups (fig 1). The decrease in \(\text{VO}_2\)\(_{\text{max}}\) related to the body weight was larger than when measured only in liters per minute. From ages 20 to 60 \(a\) the mean decrease in \(\text{VO}_2\)\(_{\text{max}}\) was 26 \% when determined as milliliters per minute \(\times\) body weight (kg) and 21 \% when measured as liters per minute. The corresponding \(\text{VO}_2\)\(_{\text{max}}\) values of group 1 were 29 and 24 \%, respectively. This group showed the greatest decrease for both values.

Stress at work

The mean \(\text{VO}_2\) during work varied between 0.91 and 1.31 l/min in the groups (groups 1—3) doing physical work, while that of the sedentary group (group 4) was 0.50 l/min (table 2). The mean aerobic stress was highest in group 1 and at about the same level in groups 2 and 3. Within the work groups the \(\text{VO}_2\) was at the same level for the three age groups. A comparison of all subjects in the three age groups showed that the two younger groups had about the same mean \(\text{VO}_2\), while that of the oldest group was somewhat higher (table 3). The absolute aerobic stress was not however statistically different between the age groups; this finding demonstrates that the \(\text{VO}_2\) during actual work remained in this sample at practically the same level as age increased.

The cumulative distribution of minutes at different stress levels showed only small differences between the age groups. The differences were more pronounced at a low rather than at a high stress level, as shown for group 1 in fig 2 a. Characteristic of group 1 was that the oldest group still worked above a stress level of 500 \%\%MET for about 5 \% of the workday.

The distribution of minutes in group 2 was markedly different from that in group 1; the cumulative curve was shifted to the left, to a lower stress level. The younger groups worked for a shorter period than the oldest group at the stress level of 300 \%\%MET (fig 2 b).

Groups 3 and 4 had different characteristics than group 2 at a low stress level. They spent about 60—70 \% of their work time sitting and standing (150 \%\%MET), which was more than double the time spent in such activities in group 2. A stress level of 300 \%\%MET was typical for groups 3 and 4. Characteristic of all the work groups was that above a stress level of 150 \%\%MET the distribution of minutes was similar in all three age groups. In summary, the stress at work was not significantly different between the age groups in this study.
Fig 2. Cumulative distribution of minutes (%) at different stress levels during a workday of three age groups within (a) group 1 and (b) group 2. In group 1 the difference between the three age groups at a stress level of 150 % MET (sitting and standing) was significant at the 5 % level. (100 % MET = basal metabolic rate).

Relative aerobic strain

The relative aerobic strain (RAS) increased with age in all groups doing mainly physical work (groups 1—3). The RAS varied from 36 to 50 % in group 1 between the ages of 20—60 a (fig 3 a). The level of RAS in group 1 was systematically higher, but the increase with age was smaller than in group 2 or 3.

The RAS in group 2 demonstrated a marked difference with age; it was estimated to increase from resting level up to 47 % at an age of 60 a. Also the confidence range was large (fig 3 b).

The regression of group 3 (r = 0.575) increased in parallel to that of group 2 and reached, at age 50, about the same level as that of group 2. The increase in RAS with age was not however statistically significant for groups 1, 2 and 3.

In contrast to the other groups, group 4, sedentary workers, showed a decrease in RAS with age (r = —0.578). With respect to all subjects, the RAS increased, but insignificantly, with age (r = 0.300).

Fig 3. Regression line and 95 % confidence limits of mean heart rate (HR) during work and age in (a) group 1, (b) group 2, (c) group 3, and (d) group 4.
Strain at work

The HRmean and age showed some characteristic differences between the work groups (fig 4 a—d). The HRmean decreased with age in groups 1 and 3. It was practically unchanged in group 4 but tended to increase with age in group 2. The largest decrease was demonstrated for group 1 ($r = -0.324$). The upper and lower 95% confidence limits in fig 4 show the range of HRmean with age, which was, in general, larger in groups 1—3, which did physical rather than mental work.

Group 2, which did mainly sensorimotor work tasks, showed an increasing tendency for HRmean with age ($r = 0.102$). At an older age their strain was at about the same level as that of the older members of group 1. When all the groups were taken into consideration, however, the changes in HRmean were not statistically significant. The HRmin and HRmax during work changed in a way similar to that of HRmean with age. In group 3, processing information into reactions, the HRmin decreased significantly with age ($r = -0.402$, $p < 0.05$).

The results of relative strain (%HRR & %HRmax) demonstrated some characteristic differences between the work groups (table 4). In group 1 all the age groups had a mean relative strain close to 40 %HRR. It dropped systematically to about 30 %HRR in group 2 and further to about 20 %HRR in group 3. The difference was smallest between groups 3 and 4, the latter having the lowest relative strain, about 16 %HRR. Within groups 1, 3 and 4 the relative strain was practically the same in the three age groups. In group 2, however, the %HRR increased from 25.3 to 31.5 and the %HRmax from 52.9 to 60.7 from the youngest to the oldest group. When all the subjects were taken into consideration, the relative strain remained at practically the same level in the three age groups: %HRR varied on an average only from 24.9 to 26.2 and %HRmax from 52.4 to 56.3.

The cumulative distribution of minutes at different heart rate levels also illustrated only small differences between the age groups. Generally, the oldest age group had more minutes at the lower heart rate levels than the younger groups. In groups 1, 3 and 4 the differences were observed mainly at a heart rate level below 90 beats/min. In contrast in group 2 the oldest group had about 10% more minutes at the heart rate level of 101—130 beats/min than the youngest group. The differences between the age groups were not statistically significant however. In summary, strain was more related to work content than to age. The differences between the age groups were small and insignificant. Contrary to other groups, group 2 showed an increasing tendency towards strain with age.

Peak loads

The relative number of minutes above the three heart rate levels of 130, 150, and 170 beats/min are given for the age and the work groups in table 5. Among the subjects doing heavy work (group 1) the duration of strain, 130 beats/min, was the...
Table 4. Relative strain during work expressed as the percentage of heart rate range (%HRR) and maximal heart rate (%HRmax) according to groups of age and work content.

shortest in the oldest (17.1%) and longest (31.7%) in the youngest group. Calculated for an 8-h workday, the mean duration was 82 and 152 min, respectively. Although a marked difference between the age groups existed, the results demonstrated that peak loads were not rare for older persons. Subjects over 50 worked 1.9% of the workday (9 min) with a heart rate of over 150 beats/min. Contrary to group 1, group 2 showed that the oldest age group had more minutes over 130 beats/min (36 min) than the youngest group (4 min). In groups 3 and 4 peak loads were not common.

Discussion

The main result of this study was that occupationally induced strain remained at
the same level in relation to capacity (%HRR and %HRmax) or tended to increase (%VO2max) with age in groups doing mainly physical work.

The decrease in VO2max with age among subjects doing heavy physical work (groups 1 & 2) is in agreement with the findings of other studies (6, 13). This result indicates that even hard physical work does not guarantee the maintenance of VO2max throughout the working age.

Because the occupational energy requirements did not decrease with age, the consequence was that the RAS tended to increase with age (fig 3). It should be emphasized, however, that although typical work tasks were selected for VO2 measurements, the values should be considered as actual stress values for heavy work and for peak loads rather than as mean values for an 8-h workday. On the other hand, the variables of strain covered a whole 8-h workday including breaks, and thus gave a more total estimation of the physical demands of the work. This difference explains why the variables of strain, eg, heart rates, were practically unchanged, while the RAS tended to increase with age.

An interesting finding was the increasing tendency of strain with age in group 2 (fig 4 b, table 4). The work content of this group mainly involved coordinating motor and sensory functions, and the group consisted of subjects from the iron and steel industry, chemical industry, a department store, and from a machine shop. The analysis of their work profile showed that they were doing about 70% static and only 30% dynamic work tasks. About 30% of the time was spent in static postures, standing in a normal or bent position. They did arm work while sitting for about 25% of the time and arm work with holding, carrying, or lifting for about 15% of the workday (12). The static postures and work tasks seemed to lead to higher strain in the older than in the younger subjects. This result confirms the findings of McDermott et al (16) that static exercise in older men induces a significantly greater level of adrenaline than in younger subjects. In group 1, "producing forces," the HRmean at work tended to decrease with age. The same phenomenon was also found in construction work, for which it has been pointed out that younger men actually perform heavier work than older ones (2).

In our study the actual work load was about the same for the older and younger men, and therefore the RAS tended to increase with age. The decreased HRmean in group 1 with age can be explained by the observations that older men had breaks of longer duration and they paused more often than the younger men doing heavy physical work.

The finding of practical importance was that both the older and younger men are exposed to peak loads. In spite of a rather spontaneously chosen level of stress and possibilities to modify the work during the 8-h period, the older men in this study were not able to avoid peak loads. Similar situations have been documented recently for different occupations (9, 20, 21, 25). In our study, during heavy phases of work, altogether 26 out of 40 subjects (65%) had a VO2 that was higher than the 33% VO2max suggested as the upper limit for continuous work (4). For the present, however, no upper limits for peak loads of short duration (4 min) have been set, but the VO2max has been given (7, 8, 10). These suggestions allow that occupational peak loads of 1—2 min should be tolerated also at the (supra)maximal level, and, eg, a peak load of 10 min is still tolerable with a level of 90% VO2max. We cannot consider this as a margin for peak loads during daily work.

Because much of the work in industry involves varying degrees of static components, the VO2max should be measured for the work being done, as Petrofsky & Lind (19) did for lifting tasks. They concluded that an average tolerable work load for lifting tasks was about 50 ± 5% VO2max; above this level heart rate and arterial lactates increase rapidly.

From the occupational health and safety point of view more attention should be paid to the study of the effects of peak loads in industry with the aim of keeping the RAS within reasonable limits with respect to age.

Acknowledgments

We wish to express our appreciation to Ms M Ahrens, Ms H Kylian, and Mr A Siuda of the Institute of Occupational
Health, Dortmund, for their valuable assistance in the data collection and to Mr M Nurminen, LSc, Ms P Fahlström, and Ms T Martelin of the Institute of Occupational Health, Helsinki, who assisted with the statistical calculations.
