An orbitally derived single-atom magnetic memory

Brian Kiraly¹, Alexander N. Rudenko¹²³, Werner M.J. van Weerdenburg¹, Daniel Wegner¹, Mikhail I. Katsnelson¹ & Alexander A. Khajetoorians¹

A magnetic atom epitomizes the scaling limit for magnetic information storage. Individual atomic spins have recently exhibited magnetic remanence, a requirement for magnetic memory. However, such memory has been only realized on thin insulating surfaces, removing potential tunability via electronic gating or exchange-driven magnetic coupling. Here, we show a previously unobserved mechanism for single-atom magnetic storage based on bistability in the orbital population, or so-called valency, of an individual Co atom on semiconducting black phosphorus (BP). Ab initio calculations reveal that distance-dependent screening from the BP surface stabilizes the two distinct valencies, each with a unique orbital population, total magnetic moment, and spatial charge density. Excellent correspondence between the measured and predicted charge densities reveal that such orbital configurations can be accessed and manipulated without a spin-sensitive readout mechanism. This orbital memory derives stability from the energetic barrier to atomic relaxation, demonstrating the potential for high-temperature single-atom information storage.
Single-atom memory represents the ultimate limit in high-density storage and a route toward quantum coherent manipulation. Of particular interest are single magnetic atoms on surfaces, which can represent a bit employing the bistability of the magnetic moment, as they offer tunable interatomic coupling and bottom-up design. While atomic spins can have long lifetimes, the key challenge has been to decrease fluctuations induced by spin-sensitive readout or scattering mechanisms utilizing robust magnetic anisotropy. The strategy toward single-atom magnetic memory has largely been to utilize certain combinations of atoms and surfaces in which the moment-bearing orbitals responsible for magnetism weakly hybridize with the environment. Ultimately, this limits the selective coupling between neighboring atoms and electronic access to the spin. Single dopants in semiconductors offer an attractive route toward atomic-scale memory and processing, with the advantage of gating while still weakly hybridizing with the localized spin. Scanning tunneling microscopy (STM) of individual non-magnetic dopants revealed bistability of an individual Co atom on semiconductor and tunable Dirac material, with a strongly anisotropic band structure and thickness-dependent band gap. To date, the magnetic properties of individual dopants in BP have not been experimentally investigated, in contrast to other Dirac materials. Here, we demonstrate a single-atom memory derived from bistability of an individual Co atom on semiconducting BP. Utilizing STM and ab initio calculations, we visualize and identify the spatially anisotropic charge densities of each state; the calculations reveal screening-stabilized orbital repopulation as the origin of bistability and further indicate unique magnetic moments for each of the valencies. We experimentally detail the effect of the local tip-induced gate potential on the switching behavior between the two. This opens up the possibility of utilizing the orbital degree of freedom for robust single-atom magnetic information storage without requiring spin-sensitive detection, as well as understanding the effect of local gating on the anisotropic charge distribution of a single atomic bit.

**Results**

**Cobalt deposition and manipulation.** The result of Co deposition on a BP surface cleaved in situ is shown in Fig. 1a, where the surface illustrates the expected buckled rhombohedral structure. Individual clean Co atoms are identified as bi-lobed butterly-like shapes due to the anisotropic extension of their charge density upon adsorption onto BP (see Supplementary Figure 1 for larger area images before and after deposition and Supplementary Figure 2 for analysis on the presence and influence of hydrogen). As seen in Fig. 1a, two types of bi-lobed Co species are observed (boxed atoms Fig. 1a), related through mirror symmetry along...
the zig-zag [010] direction, similar to single vacancies in BP\textsuperscript{29}. High-resolution analysis of the STM data (Supplementary Figure 3) reveals that the bi-lobed species reside on top sites. These species account for approximately \( \sim 98\% \) of the as-deposited atoms, indicating favorability toward top-site adsorption during low-temperature (\( T \approx 5 \) K) deposition; here, the areal density (Fig. 1a) is approximately \( 0.022 \pm 0.003 \) nm\textsuperscript{−2} (see Supplementary Figure 1).

Upon current injection with the STM tip above a voltage threshold (Fig. 1d), individual Co atoms can be manipulated from the top site to a hollow site (Fig. 1b and Supplementary Figure 4), as confirmed by atomic resolution imaging (Supplementary Figure 3). This shift of binding site involves a clear modification to the spatial charge density distribution. Surprisingly, we find that there are two unique and stable shapes of the Co atom within the same hollow site (Figs. 1c, d and 2), as exhibited by the variation in the charge density. We denote these two states as \( J_{H,\text{low}} \) and \( J_{H,\text{high}} \) (index H denotes the atomic site and high/low refers to the size of the magnetic moment shown in Fig. 2c, f). In addition to their unique spatially distributed charge density, \( J_{H,\text{high}} \) can also be distinguished by its larger apparent height in STM constant-current images (\( J_{H,\text{high}} = 176 \pm 8 \) pm, \( J_{H,\text{low}} = 132 \pm 4 \) pm at \( V_s = -400 \) mV). Switching between \( J_{H,\text{low}} \) and \( J_{H,\text{high}} \) was achieved via location-dependent current injection (Fig. 1d, e), with \( J_{H,\text{high}} \) to \( J_{H,\text{low}} \) at \( |V_s| \gtrsim 320 \) mV and \( J_{H,\text{low}} \) to \( J_{H,\text{high}} \) at \( V_s \gtrsim 320 \) mV. Notably, the switching between different hollow-site states is fully reversible, as shown in Supplementary Figure 4. However, once a Co atom is manipulated into the hollow site, we were not able to relocate it back into a top site (denoted \( J_T \), cf. Fig. 1f). Each of the three atomic configurations remained stable (as probed for measurement times up to 17 h) until intentionally perturbed. Furthermore, unlike charge switching in single dopants on semiconductors, the atomic state remains fixed after removing the applied bias\textsuperscript{16} and the charging lifetime is

![Fig. 2 Ground states of Co atoms. Ab initio calculations and state identification. To elucidate the origin of each experimentally observed Co state, we performed density functional theory (DFT) calculations for a Co atom residing on a top (Fig. 2d) and hollow site (Fig. 2e, f) to compare with experimental data (Fig. 2a–c). The calculations were carried out for monolayer BP under the generalized gradient approximation (GGA); to include the effects of local Coulomb interactions in the Co 3d orbital, calculations involving a Hubbard-U correction (GGA + U method) were also performed. Varying the Hubbard-U parameter (Supplementary Figure 5) reveals the mutually exclusive stability of two unique states with a critical value at approximately $U = 3.5$ eV, where the state favorability between $J_{\text{H,low}}$ and $J_{\text{H,high}}$ is inverted. Plotting the spatial distribution of the total charge density from the DFT calculations (Fig. 2d–f), we were able to directly associate each calculation to a corresponding constant-current STM image. The qualitative agreement is excellent and enables us to confirm the experimental binding-site analysis and to roughly approximate the effective screening parameter ($U = 0–3$ eV for $J_T$ and $J_{\text{H,low}}$; $U = 4–6$ eV for $J_{\text{H,high}}$—see Supplementary Figure 5) for the Coulomb repulsion of the Co 3d orbital. When including relaxation into the hollow-site calculations, we find that the atomic positions in the surface plane are identical (although out-of-plane distances are different—see Fig. 2h, i, and the schematic potential diagrams in Fig. 1f); namely, the experimental switching from $J_{\text{H,low}}$ to $J_{\text{H,high}}$ can neither be attributed to a change in binding site nor to different charge configurations.

The use of the Hubbard-U correction allows us to assess distance-dependent screening from the surface within the 3d shell of the Co atom. As substrate separation ($d$) is reduced, the more extended 4s orbital becomes energetically less favorable due to Pauli repulsion with the BP ligand field, while the increased screening of the 3d orbital increases its energetic favorability by decreasing Coulomb repulsion in the system. The resulting occupation of the Co 4s ($n_s$) and 3d ($n_d$) orbitals is given in Fig. 2 for each of the states (resolved into the 3d subshells in Supplementary Table 1). We find from these calculations that the relaxation ($\Delta d$) from $J_{\text{H,low}}$ to $J_{\text{H,high}}$ (Fig. 2h, i) is accompanied by a redistribution of the 4s-orbital and 3d-orbital populations (for further detail, see Supplementary Figures 6, 7, and 8). As expected, when modifying metal 3d-orbital occupancy, the total magnetic moment also changes between 1.00$\mu_B$ for $J_{\text{H,low}}$ and 2.34$\mu_B$ for $J_{\text{H,high}}$. Furthermore, calculations of the magnetic anisotropy indicate that the easy axis also changes from in-plane ($J_{\text{H,low}}$) to out-of-plane ($J_{\text{H,high}}$) (Supplementary Table 2). This suggests that the magnetic anisotropy of Co can be controlled electrically in this system. We note that similar orbital behavior has been predicted for transition-metal atoms on graphene, where multiple states (different $d$) were analogously predicted due to the reorganization of the orbital occupancies. Quantum chemistry calculations for Co on graphene further indicated that
the energy barrier between states could reach nearly 300 mV, which might explain the remarkable stability of the states observed here. This also indicates that using the orbital degree of freedom may be much more robust compared to using solely the bistability of the spin ground states.

**Tip-induced local gating.** In order to elucidate the valency switching mechanism, we studied the influence of tip-induced band bending (TIBB) on the Co states. Due to insufficient screening from charge carriers, the applied potential between tip and sample locally influences the energy of semiconductor bands; if an impurity level, shifted with the material bands, passes through the Fermi level, it will undergo an observable charging/discharging event in STM and scanning tunneling spectroscopy (STS). Such charging events resulting from TIBB can be distinguished by peaks in dI/dV whose location and intensity are strongly sensitive to the stabilization parameters. While all states demonstrate ionization events, we limit our focus in this work to the bistable states. A representative dI/dV spectrum for \( J_{H,\text{low}} \) (Fig. 2k) clearly shows a strong peak at approximately 280 mV, while the primary peak for \( J_{H,\text{high}} \) (Fig. 2l) is seen at 420 mV. In conjunction with the spectroscopic mapping (see below), the shaded regions (labeled \( q^+ \)) are identified as bias ranges where the Co species have been ionized. At biases greater than these thresholds, the atoms are non-locally ionized via the tip-induced potential along the BP surface.

To gain a more complete picture of this local surface potential, we used constant height imaging to map out the spatial dependence of the ionization as a function of bias voltage (Fig. 3a, b). The size of the isotropic disk (stepwise increase in current around the Co, or the so-called charging ring when imaged in dI/dV maps—Supplementary Figures 10 and 11) scales similarly for both states with bias according to hyperbolic contours of constant TIBB (Fig. 3c). This indicates equivalent screening from the BP for each Co configuration. Furthermore, the trend of the effective ring radii (\( r_{\text{eff}} = L/2\pi \), where \( L \) is the ring circumference) with applied bias (see also Supplementary Figure 10) indicates a flat-band condition of \( V_{FB} < -300 \text{ mV} \) (Fig. 3d). Such a condition is achievable with a tip work function of 4.0–4.1 eV. Identifying the flat-band condition and the ring-radius dependence on bias indicates that the ionization events are caused by the upward bending of states below \( E_F \) (see Fig. 3d). Theoretical calculations for both configurations reveal non-zero density of states below \( E_F \); however, \( J_{H,\text{low}} \) clearly has a strong 3d-orbital peak in the DOS between \( E_F \) and the valence band edge (\( E_v \)); consistently smaller radii for \( J_{H,\text{high}} \) compared to \( J_{H,\text{low}} \) indicate that larger TIBB is needed to ionize \( J_{H,\text{high}} \) (near 400 mV); thus, this state must lie farther from \( E_F \) than the ionized state of \( J_{H,\text{low}} \) (Supplementary Figure 10h).

**Switching dynamics and mechanism.** Upon gating the Co into the charged regimes (\( q^+ \) regions in Fig. 2k, l) with the STM tip, a discrete, bistable conductance signal, or the so-called telegraph noise, is measured on the Co atoms (Fig. 4a). The bistable states are correlated to the \( J_{H,\text{low}} \) (dark blue) and \( J_{H,\text{high}} \) (light blue) configurations of Co via independent constant-current measurements at lower negative biases (\( -400 \text{ mV} < V_s < -200 \text{ mV} \)), which do not perturb the respective states. The ability to read and
strongly diminished. This divergence indicates that given sufficient gating (above the critical bias threshold \( V^* \)), there is a strong energetic favorability in the decay mechanism from \( J_{H,\text{high}} \) to \( J_{H,\text{low}} \) (Fig. 4c). Reexamining the charging ring data from Fig. 3c, we see that this critical bias corresponds to a \( J_{H,\text{high}} \) critical charging ring radius \( r^* \) of approximately 2 nm. We also note here that the onset of telegraph switching occurs after the ring radius for \( J_{H,\text{low}} \) exceeds \( r^* \). These observations suggest that a minimum gate potential (measured as a ring radius \( r^* \)) is required to achieve efficient switching for both states. This threshold is likely related to the extension of the ionized Co charge density, which can span 2–4 nm (see Fig. 5a), as the screening for both states is nearly identical. Based on these observations, we sketch the qualitative energy diagram for the subcritical \( (r_{\text{eff}} < r^*) \) (Fig. 4c left panel) and supercritical \( (r_{\text{eff}} > r^*) \) (right panel) regimes; significantly, the only observed barrier modification is the one between ionized species \( (E^*) \).

**Discussion**

Finally, to understand the connection between the TIBB and the atomic charge density, including the subsequent impact on the switching behavior, we studied the sensitivity of the telegraph noise to the precise tip-gate position (Fig. 5). The upper panel of Fig. 5d shows the mean lifetime \( \tau_{M} = (\tau_{J,\text{high}} + \tau_{J,\text{low}})/2 \) as a function of position across the Co atom (at constant height) along two orthogonal directions (shown with darker gray ([010]) and lighter gray ([100]) arrows in Fig. 5a–c). The curves reveal contrasting results: along [100], the switching persists anisotropically to a distance of ~3.5 nm from the atom, while the switching rate decays symmetrically and significantly faster along [010] (dark gray). The differences are further reflected in the asymmetry of the states along the two distinct directions, where the zig-zag direction shows almost complete suppression of \( r_{J,\text{high}} \) (inset, Fig. 5d). The spatial dependencies of Fig. 5d closely match the anisotropy of the \( J_{H,\text{low}} \) ionized charge density (Fig. 5a), pointing to a switching mechanism based on the overlap between TIBB and the spatial extent of the charge density. We note that this switching anisotropy can be utilized to reach almost 100% directed switching probability, which is an important requirement for controlled writing of the single-atom memory.

In conclusion, we utilize a combination of atomic-scale STM/STS and DFT calculations to deduce both the valency and magnetic moment of an individual bistable Co atom at the surface of BP. We show experimentally that the atom can be switched electrically, and is an extremely robust means to store information. DFT shows excellent agreement between charge density plots and the experimentally measured STM images, further revealing that the discrete and stable states result from a shift in the relative orbital population between 4s and 3d states of the Co atom, which concomitantly changes the spin and magnetic moment. The multiple valencies are stabilized by a change of the energetic favorability in the decay mechanism from \( J_{H,\text{high}} \) to \( J_{H,\text{low}} \). The spatial dependencies of Fig. 5d closely match the anisotropy of the \( J_{H,\text{low}} \) ionized charge density (Fig. 5a), pointing to a switching mechanism based on the overlap between TIBB and the spatial extent of the charge density. We note that this switching anisotropy can be utilized to reach almost 100% directed switching probability, which is an important requirement for controlled writing of the single-atom memory.

write both Co orbital configurations confirms its utility as a binary memory; thus, we denote \( J_{H,\text{low}} \) as state 0 and \( J_{H,\text{high}} \) as state 1. To further probe the stability and favorability of these states, we studied the bias and spatial dependencies of the telegraph noise. We define \( \tau \) as the residence time for the given state, as derived in ref. \(^{35}\). Figure 4b illustrates the effect of bias at constant height. Maintaining a constant tip-sample separation, while smoothly varying the bias, results in a proportional change in the TIBB at the surface. In this manner, the influence of TIBB on the state stability can be directly measured without artifacts introduced by changing the tip-sample distance. As seen in the top panel of Fig. 4b, at lower biases \( \tau_{J,\text{low}} \) and \( \tau_{J,\text{high}} \) are nearly equivalent and strongly decay with increasing TIBB, resulting from the increased energy and flux of the tunneling electrons. However, above a threshold voltage \( V_{\text{th}} = V^* \approx 540 \text{ mV} \), the state-dependent lifetimes diverge from each other, leading to a large state favorability or what we define as asymmetry \( (A = (\tau_{J,\text{high}} - \tau_{J,\text{low}})/\tau_{J,\text{high}} + \tau_{J,\text{low}}) \) (lower panel Fig. 4b), whereby \( \tau_{J,\text{high}} \) is
states within each Co atom, thus paving the way for applications toward multi-bit registers. Third, this work also sheds light on the effect of orbital switching by local gating of individual dopants with an anisotropic charge density. Unlike previous studies of single hydrogenic impurities in semiconductors, this work reveals the significance of both TIBB and wavefunction anisotropy in the stability of a two-state system. Our calculations also show that the orientation of the magnetic anisotropy and its amplitude are significantly modified for each of the bistable valencies, indicating a method of electrically controlling the magnetic anisotropy. This motivates future experiments based on spin-resolved STM and inelastic tunneling spectroscopy, which may reveal the nature of the magnetic anisotropy as well as the spin lifetimes of each Co valency. Finally, the energy separation between orbitals can be significantly larger than magnetic anisotropy or Zeeman energies, potentially making it viable for room temperature application. As single Co atoms were also observed after annealing the sample to room temperature (Supplementary Figure 12), this may open the possibility for realistic higher temperature applications; however, subsequent experiments revealing the energy barriers between the two states will prove pivotal to ascertaining the potential value of such a system for room temperature information storage.

Methods

Scanning tunneling microscopy/scanning tunneling spectroscopy. STM/STS measurements were performed in ultrahigh vacuum (<1×10⁻10 mbar) on an Omicron low-temperature STM with a base temperature of 4.4 K, with the bias applied to the sample. Electrochemically etched W tips were used for measurements: the tips were treated in situ by electron bombardment and field emission, as well as dipped and characterized on a clean Au surface. STS was collected using a lock-in technique to directly measure dI/dV, a modulation frequency of fmod = 4.2 kHz and amplitude of Vmod = 2–6 mV were applied to the bias signal. BP crystals were provided by HQ graphene and subsequently stored in vacuum (<1×10⁻⁶ mbar) at a temperature <25 °C. The crystals were cleaved under ultrahigh vacuum conditions at pressures below 2×10⁻¹⁰ mbar, and immediately transferred to the microscope for in situ characterization. Cobalt was evaporated directly into the STM chamber with Tsub < 5 K for the entire duration of the dosing procedure.

Theoretical calculations. DFT calculations were carried out using the projected augmented-wave method as implemented in the Vienna ab initio simulation package. Exchange and correlation effects were taken into account within the spin-polarized GGA in the parametrization of Perdew–Burke–Ernzerhof. Additional Hubbard–U correction was applied to the 3d shell of Co within the GGA + U method in order to capture the effect of the distance-dependent Coulomb screening. An energy cutoff of 300 eV for the plane-wave basis and the convergence conditions at pressures below 2×10⁻¹⁰ mbar) at a temperature <25 °C. The crystals were cleaved under ultrahigh vacuum conditions at pressures below 2×10⁻¹⁰ mbar, and immediately transferred to the microscope for in situ characterization. Cobalt was evaporated directly into the STM chamber with Tsub < 5 K for the entire duration of the dosing procedure.
