ABSTRACT

The bright, short, and hard GRB 090510 was detected by all instruments aboard the Fermi and Swift satellites. The multiwavelength observations of this burst presented similar features to the Fermi-LAT-detected gamma-ray bursts. In the framework of the external shock model of early afterglow, a leptonic scenario that evolves in a homogeneous medium is proposed to revisit GRB 090510 and explain the multiwavelength light curve observations presented in this burst. These observations are consistent with the evolution of a jet before and after the jet break. The long-lasting LAT, X-ray, and optical fluxes are explained in the synchrotron emission from the adiabatic forward shock. Synchrotron self-Compton emission from the reverse shock is consistent with the bright LAT peak provided that the progenitor environment is entrained with strong magnetic fields. It could provide compelling evidence of magnetic field amplification in the neutron star merger.

Key words: gamma-ray burst: individual (GRB 090510) – ISM: general – magnetic fields – radiation mechanisms: non-thermal

1. INTRODUCTION

Gamma-ray bursts (GRBs) are intense and non-repeating flashes with an extensive range of spectral and temporal properties. Based on the standard GRB durations, two dominant progenitor populations have been highly suggested, short ($T_{90} < 2$ s) and long ($T_{90} > 2$ s) GRBs. Despite the spectacular pace of discovery for long GRBs (lGRBs), the study of short GRBs (sGRBs) has proved much more challenging (Berger 2014). The most popular progenitor model associated with sGRBs is the merger of compact object binaries comprising a neutron star binary (NS–NS) or a neutron star–black hole (NS–BH) (Eichler et al. 1989; Narayan et al. 1992; Lee et al. 2004, 2005b; Lee & Ramirez-Ruiz 2007; Nakar 2007). LGRBs have been commonly associated to core collapse of massive stars leading to supernovae (CCSNe) of type Ib, c, and II (Woosley & Bloom 2006; Hjorth & Bloom 2012, p. 169; Hjorth et al. 2003). For lGRBs, the strong gamma-ray polarization (Coburn & Boggs 2003, Willis et al. 2005, but see Rutledge & Fox 2004 and more recently Yonetoku et al. 2011) and a stronger magnetic field in reverse shock (RS) rather than in forward shock (FS) as a result of a full description of a dozen lGRBs (Zhang et al. 2003; Fan et al. 2004; Zhang & Kobayashi 2005; Kobayashi et al. 2007; Fraija 2015), have supported the idea that the central engines of lGRBs could be endowed with primordial magnetic fields (Usov 1992; Wheeler et al. 2000). In the framework of sGRBs, the question of what field strengths could be reached in a merger remnant before it collapses to a BH has so far remained unanswered, and there is no evidence of magnetization in the jet having been found. Simulations have shown that during the merger, the magnetic field strength can increase up to $10^{16}$ G. The growth emerges from the transfer of hydrodynamical kinetic energy to electromagnetic energy via Kevin–Helmholtz instabilities and turbulent amplification (Price & Rosswog 2006; Giacomazzo et al. 2009; Obergaulinger et al. 2010; Zrake & MacFadyen 2013).

The bright, short, and hard GRB 090510 was detected by the Fermi and Swift satellites (De Pasquale et al. 2010). During the first second after the Gamma-Ray Burst Monitor (GBM) trigger at 00:22:59.97 UT, LAT detected 62 events with energies $>100$ MeV, 12 events with energies $>1$ GeV, and one event (the most energetic photon) with $30.5\pm 5.6$ GeV at 0.829 s. The observations performed with the Very Large Telescope (Rau et al. 2009; McBreen et al. 2010) provided a spectroscopic redshift of $z = 0.903$ as measured [O II] and [H [beta]] emission lines. Considering this redshift, the isotropic-equivalent energy in the range of 10 keV–30 GeV is $E \approx (1.08 \pm 0.06) \times 10^{53}$ erg. Reﬁned analysis of BAT data found a duration of prompt emission $T_{90} = 0.3 \pm 0.1$ s (Ukwatta et al. 2009; De Pasquale et al. 2010). The analysis of the prompt emission at latter times ($\sim 0.3$ s) showed a bright peak in the LAT light curve (LC) above 100 MeV followed by a temporally extended LAT, X-ray and optical emission. These broadband observations by X-ray Telescope (XRT) and Ultra Violet and Optical Telescope (UVOT) instruments on board Swift, were described by broken power laws with a break at $\sim 1.5 \times 10^{3}$ s and LAT on board Fermi, was fitted with a simple power law extended from $\sim 1$ s to $\sim 200$ s. In the framework of synchrotron radiation of FS, a wide set of leptonic scenarios have been explored to explain the high-energy photons ($\geq 100$ MeV) present in GRB 090510 (Kumar & Barniol Duran 2009, 2010; Corsi et al. 2010; De Pasquale et al. 2010; Ghirlanda et al. 2010; Ghisellini et al. 2010; Piran & Nakar 2010; Razzano et al. 2010; He et al. 2011; Liu & Wang 2011). In particular, He et al. 2011 described not only LAT, but X-ray and optical observations from an early adiabatic FS emission in a model including a jet break. The authors argued that the early emission ($t < 2$ s) was inconsistent with the standard RS. They explored the RS synchrotron emission in the thin-shell case, when the flux peak at the crossing time was longer than the duration of the prompt emission ($t_{\text{dec}} > T_{90}$). They compared the RS synchrotron flux to FS synchrotron flux at 1 GeV, finding that this ratio was less than unity when the ejecta were not magnetized ($\sigma \ll 1$) and both the RS and FS synchrotron spectra were in the slow-
cooling regime. After fitting the multiwavelength observations, they found that the values of density, electron and magnetic microphysical parameters lie in the range $n \sim 10^{-3}$$-10^{-6}$ cm$^{-3}$, $\epsilon_e \sim 0.2$–0.6 and $\epsilon_B \sim 10^{-5}$–$10^{-2}$, respectively.

Recently, Fraija (2015) and Fraija et al. (2016) proposed an early afterglow model with inhomogeneous density to explain the multiwavelength afterglow observations of GRB 110731A and GRB 130427A. As a result of good fits of the long-lasting LAT, X-ray, and optical fluxes with synchrotron radiation from the adiabatic FS and the bright LAT peak with synchrotron self-Compton (SSC) emission from RS in the thick-shell case, the author found that the central engine must be entrained with strong magnetic fields. In this paper, we extend this early afterglow model to be evolved in a homogeneous medium and revisit GRB 090510 to describe the long-lasting emission and the bright peak flux present in the LAT LC.

2. LIGHT CURVES FROM EXTERNAL SHOCKS

In the following subsections, we will show the LCs from RS and FS when electrons are accelerated and cooled down by synchrotron and Compton scattering emissions.

2.1. LCs from FS Emission

The dynamics of the afterglow for a spherical ultrarelativistic and adiabatic shell propagating into a homogeneous density is analyzed through the deceleration time, the energy of the shock, the bulk Lorentz factor, and the radius at which the mass swept up (Sari & Piran 1995; Sari et al. 1998; Sari & Piran 1999; Kumar & Piran 2000). Comparing the time scale of the synchrotron process with the deceleration time of the ejecta and the acceleration time of electrons, the synchrotron spectral breaks and the maximum flux are calculated in Sari et al. (1998).

Requiring the observed synchrotron spectrum for the fast- and slow-cooling regime and the synchrotron spectral breaks (Sari et al. 1998), the temporal decay fluxes can be obtained as a function of energy. Then, the LC obtained in the fast- and slow-cooling regime are

$$F_{\nu,f} = \begin{cases} A_{\nu f} \frac{\nu}{t} (E_{\gamma f}^2)^{\frac{3}{2}}, & E_{\gamma f} < E_{\gamma f,m}, \\
A_{\nu f} \frac{\nu}{t} (E_{\gamma f}^2)^{\frac{1}{2}}, & E_{\gamma f} < E_{\gamma f,m}, \\
A_{\nu f} \nu^{-\frac{3}{2}} (E_{\gamma f}^2)^{\frac{1}{2}}, & E_{\gamma f} < E_{\gamma f,m}, \\
A_{\nu f} \nu^{-\frac{1}{2}} (E_{\gamma f}^2)^{\frac{1}{2}}, & E_{\gamma f} < E_{\gamma f,m}, \\
A_{\nu f} \nu^{-\frac{1}{2}} (E_{\gamma f}^2)^{-\frac{1}{2}}, & E_{\gamma f} < E_{\gamma f,m} \\
\end{cases}$$

where $A_{\nu f}$ are given in the Appendix.

When the bulk Lorentz factor drops below the inverse of the jet opening angle $\Gamma_j \sim \theta_j^{-1}$, a break (at the jet-break time) in the LC is observed, because the surface that we can observe has grown larger than the surface that radiates. This episode is evident in LCs, exhibiting a break in the afterglow observations (Sari et al. 1999). Therefore, afterglow emission can be affected by the evolution of the jet before and after it slows down and spreads laterally.

Synchrotron photons can be upscattered by Fermi-accelerated electrons (e.g., Sacahui et al. 2012; Véres & Mészáros 2014). Using the synchrotron spectral breaks (Sari et al. 1998), the SSC spectral breaks and the maximum flux are computed in Sari & Esin (2001).

2.2. LCs from RS Emission

We consider the thick-shell case for which the shell is significantly decelerated by the RS (i.e., the bulk Lorentz factor is higher that the critical Lorentz factor $\Gamma_c$) (Zhang & Kobayashi 2005; Fraija et al. 2012). Numerical analysis performed by Fan et al. (2004) revealed that for the particular value of the magnetization parameter $\sigma \approx 1$, which is defined as the ratio of Poynting flux to matter energy flux $\sigma = L_{PF}/L_{kin} \approx c_{B,F}$ (Fan et al. 2004; Kobayashi & Zhang 2007), the shock crossing time becomes $t_d \approx T_{90}/6$.

The synchrotron and SSC spectral breaks, and fluxes are determined by the synchrotron spectral evolution between RS and FS for $R_e = 1$ (Zhang & Kobayashi 2005; Fraija 2015; Fraija et al. 2016).

Before the RS crosses a thick shell, the hydrodynamic variables as a function of the observer time $t \propto R_e^2$ vary as (Kobayashi et al. 2007): the bulk Lorentz factor $\Gamma_f \propto t^{-1/4}$, the homogeneous density $n \propto t^{-3/4}$, the pressure $p \propto t^{-1/2}$, and the total number of the shocked electrons $N_e \propto t$. Taking into account the evolution of the magnetic field $B_{f} \propto t^{-1/4}$, the minimum Lorentz factor $\gamma_{e,c,f} \propto t^{-1/4}$ and the cooling Lorentz factor $\gamma_{e,c,r} \propto B_{r}^{-2} \Gamma_r^{-1} \propto t^{1/4}$, then the synchrotron spectral breaks and the maximum flux for $t < T_{90}$ evolve as

$$E_{\gamma,mc, f} \propto B_{r} \Gamma_{f}^{-2} \Gamma_{r}^{-1} \propto t^{1/4},$$

and for the slow-cooling regime

$$F_{\nu,c} \propto \begin{cases} t^{-1} (E_{\gamma,c}^{SSC})^{-\frac{3}{2}}, & E_{\gamma,c} < E_{\gamma,c,m}, \\
F_{\nu,c} \propto \begin{cases} t^{-1} (E_{\gamma,c}^{SSC})^{-\frac{3}{2}}, & E_{\gamma,c} < E_{\gamma,c,m}, \\
\end{cases}$$

and for the slow-cooling regime

$$F_{\nu,c} \propto \begin{cases} t^{-1} (E_{\gamma,c}^{SSC})^{-\frac{3}{2}}, & E_{\gamma,c} < E_{\gamma,c,m}, \\
F_{\nu,c} \propto \begin{cases} t^{-1} (E_{\gamma,c}^{SSC})^{-\frac{3}{2}}, & E_{\gamma,c} < E_{\gamma,c,m}, \\
\end{cases}$$

Once the RS has crossed the thick shell, the hydrodynamic variables as a function of the observer time $t \propto R_e^3$ vary as (Kobayashi et al. 2007): the bulk Lorentz factor $\Gamma_f \propto t^{-7/16}$, the homogeneous density $n \propto t^{-13/16}$, the pressure $p \propto t^{-13/12}$, and the total number of the shocked electrons $N_e \propto t^6$. Taking into account the evolution of the magnetic field $B_{r} \propto t^{-12/24}$, the minimum Lorentz factor $\gamma_{e,c,r} \propto t^{-13/48}$, and the cooling Lorentz factor $\gamma_{e,c,r} \propto B_{r}^{-2} \Gamma_r^{-1} \propto t^{25/48}$, the synchrotron
spectral breaks and the maximum flux for \( t > T_{90} \) evolve as
\[
E_{\gamma,\text{max},r} \propto B_r \Gamma_{\gamma,\text{m.r.}}^2 \propto t^{-73/48},
\]
\[
E_{\gamma,\text{max},r} \propto B_r^{-2} \Gamma_{\gamma,\text{m.r.}}^{-1} \propto t^{-1/16},
\]
\[
F_{\gamma,\text{max},r} \propto N_r B_r \Gamma_{\gamma} \propto t^{-47/48}.
\]
(6)

Considering the inverse Compton scattering equations and Equation (6), we get that the SSC LC for the fast-cooling regime is
\[
F_{\nu,\gamma}^{\text{SSC}} \propto \begin{cases} 
\frac{t^{-\frac{7}{4}}}{(E_{\gamma}^{\text{SSC}})^{\frac{7}{4}}}, & E_{\gamma}^{\text{SSC}} < E_{\gamma,\text{c.r.}}^{\text{SSC}}, \\
\frac{t^{-\frac{7}{4}}}{(E_{\gamma}^{\text{SSC}})^{\frac{7}{4}}}, & E_{\gamma}^{\text{SSC}} < E_{\gamma,\text{m.r.}}^{\text{SSC}}, \\
\frac{4p-1}{4} (E_{\gamma}^{\text{SSC}})^{\frac{4p-1}{4}}, & E_{\gamma}^{\text{SSC}} < E_{\gamma}^{\text{SSC}},
\end{cases}
\]
(7)

and for the slow-cooling regime is
\[
F_{\nu,\gamma}^{\text{SSC}} \propto \begin{cases} 
\frac{t^{-\frac{16}{3}}}{(E_{\gamma}^{\text{SSC}})^{\frac{16}{3}}}, & E_{\gamma}^{\text{SSC}} < E_{\gamma,\text{c.r.}}^{\text{SSC}}, \\
\frac{t^{-\frac{16}{3}}}{(E_{\gamma}^{\text{SSC}})^{\frac{16}{3}}}, & E_{\gamma}^{\text{SSC}} < E_{\gamma,\text{m.r.}}^{\text{SSC}}, \\
\frac{4p-1}{4} (E_{\gamma}^{\text{SSC}})^{\frac{4p-1}{4}}, & E_{\gamma}^{\text{SSC}} < E_{\gamma}.\end{cases}
\]
(8)

Following Kobayashi & Zhang (2003), the peak in the SSC flux, for the fast-cooling regime, can be written as
\[
F_{\nu,\gamma}^{\text{SSC,peak}} \sim F_{\nu,\gamma}^{\text{SSC}} \propto \frac{t^{-\frac{7}{4}}}{(E_{\gamma}^{\text{SSC}})^{\frac{7}{4}}}, \quad t^{-\frac{7}{4}} < t < T_{90},
\]
(9)

3. APPLICATION: GRB 090510

GRB 090510 was detected on 2009 May 10 by both instruments aboard Fermi; the GBM and LAT (Guiriec et al. 2009; Ohno & Pelassa 2009) and the three instruments aboard Swift: BAT, XRT and UVOT (Hoversten et al. 2009; Ukwatta et al. 2009; De Pasquale et al. 2010). The LAT instrument observed a bright peak at 0.3 s followed by an extended emission (above 100 MeV) during 200 s after the GBM trigger. The extended component was described with a simple power law with a temporal decay index \( \alpha_{\text{LAT}} = 1.38 \pm 0.07 \).

At 00:23:00 UT, 2009 May 10, the Swift BAT triggered on GRB 090510 (Hoversten et al. 2009). Refined analysis of BAT data found a duration of prompt emission \( T_{90} = 0.3 \pm 0.1 \) s (Ukwatta et al. 2009; De Pasquale et al. 2010). The Swift XRT started observing the X-ray afterglow of GRB 090510 at 98 s after the GBM trigger. A broken power law was used to fit the LC. The best-fit parameters found were: an early decay slope \( \alpha_{X,1} = 0.74 \pm 0.03 \), a break time \( t_{br,X} = 1.43^{+0.06}_{-0.05} \times 10^3 \) s, and a late decay slope \( \alpha_{X,2} = 2.18 \pm 0.10 \). The Swift UVOT began detecting this burst at 97 s after the initial trigger. This instrument measured the position of the optical afterglow counterpart to be R.A. (J2000), decl. (J2000) = 22h14m12.5s, \(-26\)°34'59.2" (Kuin & Hoversten 2009). The optical LC was well fitted by a broken power law. In this optical band, the best-fit parameters found were: an early decay slope \( \alpha_{\text{opt},1} = -0.50^{+0.08}_{-0.13} \), a break time \( t_{br,\text{opt}} = 1.58^{+0.46}_{-0.37} \times 10^3 \) s, and a late decay slope \( \alpha_{\text{opt},2} = 1.13^{+0.11}_{-0.13} \).

We summarize in Table 1 the relevant observation parameters for GRB 090510.

By considering the quantities inferred from observations given in Table 1, the isotropic-equivalent kinetic energy \( E_{k,\text{iso}} = E_{\gamma,\text{iso}}/\eta = 10^{53} \) erg with \( \eta \approx 0.2 \) the kinetic energy efficiency to convert bulk kinetic energy to \( \gamma \)-ray energy \( E_{\gamma,\text{iso}} \) and using the method of Chi-square minimization (Brun & Rademakers 1997), we obtain the values of density, bulk, Lorentz factors and the microphysical parameters that reproduce the multiwavelength (LAT, XRT, and UVOT) afterglow observations with the spectral index of electron distribution \( p = 2.2 \) and \( \gamma_{\text{dec}} = 0.3 \). The value of this spectral index was chosen linking the observed slopes of temporal decays of LAT \( (\alpha_{\text{LAT}} = 1.125; \ He \ et \ al. \ 2011) \) and X-ray \( (\alpha_{X,1} = 0.74 \) and \( \alpha_{X,2} = 2.18; \ De \ Pasquale \ et \ al. \ 2010) \) fluxes with the synchrotron emission LCs (Equations (1) and (2))

\[
\alpha_{\text{LAT}} = (3p - 2)/4, \quad \alpha_{X,1} = (3p - 3)/4 \quad \text{and} \quad \alpha_{X,2} = p,
\]

respectively. LAT detections are modeled by synchrotron emission from FS and SSC radiation from RS; the long-lasting flux at 100 s requiring synchrotron LC in the fast-cooling regime (Equation (1)) and the bright peak flux at 0.3 s with SSC radiation, for ultra-relativistic electrons radiating photons in the energy range of 0.1-4 GeV (De Pasquale et al. 2010). The X-ray emission at \( t < 1.43 \) ks is described using the synchrotron LC in the slow-cooling regime (Equation (2)) at \( t = 100 \) s for electrons giving off at \( E_{\gamma,f} = 1 \) keV, and an optical component at \( t < 1.58 \) ks using the LC in the slow-cooling regime (Equation (2)) at \( t = 100 \) s for \( E_{\gamma,f} = 1 \) ev. The values of microphysical parameters \( \epsilon_{\gamma,f}, \epsilon_{e}, \) and the density in the range \( 10^{-16} \leq n \leq 10^{-11} \) cm\(^{-3}\) that describe the long-lasting components of LAT, X-ray, and optical data up to \( \sim 1.5 \times 10^3 \) s are plotted in Figure 1, and the parameters \( \epsilon_{\gamma,f}, \epsilon_{e}, \) and \( 10^{-6} \leq n \leq 10^{-11} \) cm\(^{-3}\) that explain the LAT-peaked data are plotted in Figure 2. After \( \sim 1.5 \times 10^3 \) s, we use the post jet-break equations for the LC, \( F_{\nu,j,b} \propto t^{-\gamma} \) for X-ray and \( \gamma t^{-\gamma} \) for optical flux (e.g., Kumar & Barniol Duran 2010).

Table 1

| Quantities Inferred from the Multiwavelength Afterglow Observation of GRB 090510 |
|-------------------------------------------------------------|
| **X-Ray flux** | **Optical flux** | **References.** |
| **Power index** | \( \alpha_{\text{LAT},2} \sim 0.74 \pm 0.03 \) | (1) Ackermann et al. (2010), (2) Rau et al. (2009), (3) McBreen et al. (2010), (4) Ukwatta et al. (2009), De Pasquale et al. (2010). |
| **Initial time after the GBM trigger (s)** | \( t_{br,\text{opt}} \sim 1.58^{+0.46}_{-0.37} \times 10^3 \) | |
| **Duration of prompt emission (s)** | \( T_{90} \sim 0.3 \pm 0.1 \) | |
| **Duration of bright peak (s)** | \( \epsilon \sim 0.903 \pm 0.001 \) | |
| **Isotropy (erg)** | \( E_{\gamma,\text{iso}} \sim 0.18 \pm 0.06 \) \times 10^{53} | |
| **Redshift** | \( z \sim 0.903 \pm 0.001 \) | |
the long-lasting LAT component (in the energy range of 0.1–4 GeV at 100 s), those in purple present those parameters that describe the X-ray emission for $t < 1.43$ ks (at 1 keV and 100 s), and the green ones those parameters that explain the optical component for $t < 1.58$ ks (at 1 eV and 100 s). The black lines over the area in orange represent the photon fluxes emitted at 1 GeV, 500, 200, and 100 MeV. The zones’ intersection (orange, purple, and green) correspond to the set
of parameters that describe more than one component. Then, it is possible to find a set of parameters (intersected zones) that explain the LAT, X-ray, and optical components for the range of density values considered. For instance, in the panel with the $n = 10^{-1} \text{ cm}^{-3}$ label, the long-lasting LAT, X-ray, and optical components are described by the microphysical parameters around $\epsilon_e \sim 0.44$ and $\epsilon_{B_f} \sim 10^{-5.3}$ for ultra-relativistic electrons giving off at $\sim 1 \text{ GeV}$. As shown in Figure 1, these surfaces are shifted to smaller values of $\epsilon_e$ and higher values of $\epsilon_{B_f}$ as density decreases. As can be seen, the LAT component does not give a constrain on $\epsilon_{B_f}$, since the orange zone is very "flat." This is because the LAT energy band is above the

Figure 2. Values of microphysical parameters ($\epsilon_{B_f}$ and $\epsilon_e$) obtained through SSC emission from RS that describe the bright LAT-peak flux. The value of $\epsilon_e$ for each density obtained as a good fit to the extended LAT, X-ray, and optical fluxes of FS (see Figure 1) is highlighted by a dashed line.
cooling energy, and thus, the flux is almost independent on $\varepsilon_B$ (Kumar 2000). Similarly, due to the synchrotron emission with $E_{\gamma,s} \approx E_{\gamma,c,f}$ not being dependent on the density, the orange region does not change when the density varies (e.g., Kumar 2000).

Figure 2 exhibits regions in orange. Each of these regions shows the set of microphysical parameters ($\varepsilon_{B,i}$ and $\varepsilon_f$) for the density in the range of $10^{-6} \leq n \leq 10^{-1} \text{ cm}^{-3}$ that explain the bright LAT-peak component. The black lines over the region in orange represent the photon emissions radiated at 1 GeV, 500, 200, and 100 MeV. The value of $\varepsilon_f$ for each density obtained as a good fit to the long-lasting LAT, X-ray, and optical data (see Figure 1) and is highlighted by a dashed line. To constrain the pair of values of $\varepsilon_f$ and $n$ that describe the bright LAT-peak data, we plot the break photon energy of SSC emission from RS as a function of magnetic field equipartition, as shown Figure 3. This figure shows that the break SSC energy lies in the energy range of the LAT instrument only for $n = 10^{-1} \text{ cm}^{-3}$ and $\varepsilon_{B,i} \gtrsim 0.01$. Comparing Figures 2 and 3, it can be seen that for $n = 10^{-1} \text{ cm}^{-3}$, $\varepsilon_f = 0.43$, and $0.05 \lesssim \varepsilon_{B,i} \lesssim 0.3$, ultra-relativistic electrons radiating photons at $E_{\gamma,sc} \approx 100 \text{ MeV}$ would describe the bright peak in the LAT data. For this case, the SSC radiation from RS around the peak ($E_{\gamma,sc} = E_{\gamma,i,m,f} \approx 100 \text{ MeV}$), would have a rise flux $F_{\nu,sc} \propto t^{\alpha_{sc}}$ and temporal decay $F_{\nu,sc} \propto t^{-\beta_{sc}}$ (Equations (4) and (7)).

With the value of density $n = 10^{-1} \text{ cm}^{-3}$, we found that the bulk Lorentz factor is $\Gamma_s \approx 3000 > \Gamma_i$ and the RS evolves in the thick-shell case with a critical Lorentz factor $\Gamma_c = 1300$. When the bulk Lorentz factor drops below the inverse of the jet opening angle $\theta_j \approx 0.772$ (Kumar & Barniol Duran 2010), we see a break in the LC (Sari et al. 1999), which corresponds to a jet-break time of $t_{\text{jet}} \approx 1.5 \times 10^5 \text{s}$.

In Table 2, we sum up the microphysical parameters, densities, and bulk Lorentz factors found after modeling the multiwavelength afterglow observed in GRB 090510, as shown in Figure 4. This figure displays all contributions to the multiwavelength afterglow observations of GRB 090510. From the value of the magnetic microphysical parameter of RS, the magnetization parameter is $\sigma \approx 0.3$. This result agrees with the observed bright peak in the LAT flux. If the GRB outflow had been highly magnetized ($\sigma \gg 1$) when it crossed the RS, particle acceleration may be very inefficient, as pointed out by Sironi & Spitkovsky (2011) and the RS would have been suppressed (Zhang & Kobayashi 2005). Therefore, a moderate magnetization ($\sigma \approx 1$) is needed (as found in this work) to obtain a bright peak from RS (Kumar & Panaitescu 2003; Zhang et al. 2003; Fan et al. 2004). Similarly, comparing the microphysical parameter for the magnetic field in both shocks, it is possible to observe that the magnetic field in both shocks is different $B_i = R_{\text{IC}}^{1/2} B_f \approx 200 B_f$, thus indicating that the ejecta carry a significant magnetic field.

Based on the shock jump conditions (Zhang & Kobayashi 2005) with the values found of the magnetization parameter $\sigma \approx 0.3$ and the FS bulk Lorentz factor $\Gamma_f = \gamma_2 \approx 520$, the relative Lorentz factor of the RS upstream and downstream and the initial Lorentz factor around the discontinuity are $\gamma_{3i} \approx 500$ and $\gamma_4 \approx 5 \times 10^5$, respectively. The high value obtained of $\gamma_4$ is due to the fact that similar densities $n_1 = n_4$ were considered (Zhang & Kobayashi 2005). If we had allowed for a different ratio of densities, then this value would have been smaller. The value found for similar densities could be explained in the context of the dynamical evolution of a hybrid relativistic outflow with arbitrary magnetization (Gao & Zhang 2015). In addition, the value of a magnetization parameter $\sigma \sim 0.3$ at the deceleration radius indicates that before deceleration the jet must also have dissipated a significant amount of Poynting flux during the prompt emission phase. A candidate process to make this happen would be the so-called internal collision-induced magnetic reconnection and turbulence model proposed by Zhang & Yan (2011).

Using the values of parameters reported in Table 2, we have derived the observable quantities, as shown in Table 3. The
values of the critical Lorentz factor computed in our model is self-consistent with the fact that the bright LAT peak occurs at the end of the prompt phase and the RS evolves in the thick-shell case ($\Gamma_r > \Gamma_f$).

The synchrotron self-absorption energies from FS and RS are in the weak self-absorption regime. Then, as observed in LC of GRB 090510, there is no thermal peak in the synchrotron spectrum (Kobayashi et al. 2004; Gao et al. 2013).

Due to the early LAT component being present between 0.1–4 GeV and the break energy at the KN regime being 12.11 GeV, the LC of RS SSC derived here (Equation (7)) and used to describe the bright LAT peak is not altered. Although we describe the long-lasting LAT component in the energy range of 0.1–4 GeV with synchrotron radiation from FS, the 12 events with energies $\gtrsim 1$ GeV and the most energetic event with 30.5$^{+3.8}_{-1.6}$ GeV at 0.829 s, we cannot disregard that these photons can have their origin in SSC emission from FS (e.g., Wang et al. 2013; Beniamini et al. 2015). It is worth noting that bursts with sub-TeV photons at dozens of seconds from the trigger might be interpreted as SSC radiation from FS and be detected by TeV $\gamma$-ray observatories as the High Altitude Water Cherenkov observatory (HAWC) (Abeysekara et al. 2012, 2014).

4. CONCLUSIONS

We have introduced an external shock model to explain the multiwavelength afterglow observations present in GRB 090510. Taking into account that the LAT-peak flux occurs at the end of the prompt emission, we have considered that the ejecta propagating in the homogeneous medium are decelerated early at $\sim 0.3$ s and the RS evolves in the thick-shell regime.

Under the standard assumptions that the magnetic field and electron microphysical parameters are constant, we have modeled the long-lasting LAT, X-ray, and optical components up to the break time ($t_{br} \sim 1.5 \times 10^3$ s) with the synchrotron radiation LC from FS and after this break time, the LC of the spreading jet has been used to fit the X-ray and optical fluxes. The bright LAT-peak component has been described through LCs of SSC emission from RS (Equations (4) and (7)). We have plotted the set of values of density and microphysical parameters that describes these observations, as shown in Figures 1, 2, and 3. Considering the number density in the range $10^{-6} \leq n \leq 10^{-1}$ cm$^{-3}$, the microphysical parameters lie in the range $10^{-3.5} \leq \epsilon_B \leq 0.7$ and $10^{-1.5} \leq \epsilon_e \leq 0.48$ for FS and in the RS, the microphysical parameters lie in the range $10^{-4.0} \leq \epsilon_B, r \leq 0.9$ and $10^{-1.6} \leq \epsilon_e \leq 0.45$. From RS, one can see that density values lower than $n \leq 10^{-3}$ cm$^{-3}$ require SSC energies higher than 1 GeV ($E_{\gamma, SS} \geq 1$ GeV). In this case, it is not possible with plausible parameter values to reach these SSC energies. Hence, the standard RS cannot contribute to the LAT emission, thus reproducing the results obtained by He et al. (2011). Otherwise, requiring the temporal and spectral description of the bright LAT-peak flux, we get the number density $n = 10^{-1}$ cm$^{-3}$ and the values of parameters $\epsilon_e = 0.44$, $\epsilon_B = 10^{-5.5}$, and $\epsilon_{BR} = 0.24$. The observed X-ray and UVOT flux decay indices after the $t_{br}$ are $\alpha_{X, 2} = 2.18 \pm 0.10$ and $\alpha_{opt, 2} = 1.13^{+0.11}_{-0.13}$, respectively, which are softer than the electron synchrotron radiation. These temporal decays are more consistent with the evolution of the jet after it slows down and spreads for X-ray rather than optical data. The bulk Lorentz factor obtained at the $t_{br}$ is $\sim 120$ that corresponds to a jet opening angle of $0.7^2$.

It is worth noting that in the current model the differences between the values of SSC and synchrotron spectral breaks at FS and RS come from the magnetic energy fractions given at both shocks. Comparing the strength of magnetic fields at FS ($\sim 3$ G) and RS ($\sim 600$ G), we can see that the magnetic field in the RS region is stronger ($\sim 200$ times) than in the FS region, which indicates that the ejecta are magnetized. The magnetization of the ejecta modifies the temporal characteristics of the bright LAT-peak component; it becomes much shorter than $\leq 0.3$ s (Fan et al. 2004). Therefore, the short and bright LAT-peak component at the end of the prompt emission indicates that the mechanism of jet production is due to magnetic processes instead of neutrino annihilations, thus giving evidence of the magnetic field amplification in neutron star mergers in GRB 090510. In principle, these two mechanisms (neutrino annihilation and magnetic processes) could supply the outflow with different energies. The outflows driven by neutrino annihilation can provide $10^{48}$ erg as shown in GRB 050509B (Lee et al. 2005a), whereas the magnetic mechanism could supply $10^{51}$ erg or more (Narayan et al. 1992; Rosswog et al. 2003) as in the case for this burst. In addition, based on compact object binary population synthesis models, Perna & Belczynski (2002) argued that such a merger tends to happen in lower-density environments $\sim 0.1$ cm$^{-3}$ which is in accordance with our results.

Some authors have suggested that the fireball wind, which is connected to the GRB central engine, a black hole (BH)—torus system, or a rapidly rotating magnetar may be endowed with "primordial" magnetic fields (Usov 1992; Mészáros & Rees 1997; Wheeler et al. 2000). The energy requirement (isotropic-equivalent luminosities $L_{\gamma, iso} \geq 10^{52}$ erg s$^{-1}$) demands magnetic fields at the base in excess of $B \sim 10^{15}$ G. In the LAT era, GRB110731A (Ackermann et al. 2013) and GRB130427A (Ackermann et al. 2014) were detected from optical to GeV energy range and were shown to have in the LAT LC temporally extended fluxes lasting hundreds of seconds in coincidence with short-lasting bright peaks. Fraija (2015) and Fraija et al. (2016) showed that both components could be interpreted as synchrotron and SSC emissions from the forward and reverse shocks, respectively, provided that the central engines were entrained with a significant magnetic field.
The authors found that the strength of magnetic fields in the RS region were stronger (~50 and 66 times, respectively) than in the FS region. Comparing the isotropic total energies and the values found for magnetic field in the RS for GRB110731A, GRB130427A, and GRB090510, it can be seen that GRB090510 demands more magnetic fields at the base of the jet. For instance, considering a typical size of a fireball for sGRBs ($r_t \sim 10^{15}$ cm; Lee et al. 2004, 2005b; Nakar 2007) and total isotropic energy $10^{53}$ erg, the magnetic field at the initial time is roughly calculated as $B \approx \sqrt{8\epsilon_{\text{B}}E_{\gamma,\text{iso}}/t_t^3} \approx \sqrt{8\epsilon_{\text{B}}10^{52}}$ G which is much stronger than the typical magnetic field of the neutron star $\sim 10^{12}$ G. Here, $\epsilon_{\text{B}}$, is the initial fraction of total energy given to the magnetic field. We have shown that the presence not only in GRB 090510, but in future detections of sGRBs with the same features could offer evidence of the magnetic field amplification during the merger of NS–NS.

The main difference between the current model and the model proposed by He et al. (2011) is that the RS evolves in the thick-shell case and the ejecta must be magnetized in order to obtain a good description of the bright LAT-peak flux. We emphasize that in the external shock model of early afterglow with the suitable values of the parameters obtained in this work, the magnetized RS SSC emission can explain successfully the early LAT data. Recently, Gao et al. (2015) performed a morphological analysis of the early optical light curves in some GRBs including GRB 090510 (Pelassa & Ohno 2010). As successful descriptions of optical light curves, they found values of microphysical parameters similar to those obtained in this work, indicating that the jet was magnetized.

Using the MeV prompt emission (GBM) data and assuming a constant radiative efficiency, Maxham et al. (2011) were able to track the energy accumulation in the external shock with an internal/external shell model code. The authors analyzed some LAT bursts (including GRB 090510) and suggested that the high-energy emission present in most of the LAT bursts during the prompt phase is most likely a superposition of a gradually enhancing external shock component and a dominant emission component that is of an internal origin. Similarly, Zhang et al. (2011) performed a comprehensive analysis of Fermi GRB data to study the possible origins of LAT/GBM GRBs. For this purpose, they derived LAT/GBM LC for GRB090510 (see Figure 8 in Zhang et al. 2011). The lowest panel shows that GeV emission peaks at an epoch when the MeV emission has already decayed. Therefore, at the GeV emission peak the external shock is likely not undergoing energy injection and has entered the deceleration phase. Additionally, LAT/GBM LCs of some bursts derived in Zhang et al. (2011) exhibit coincidences between peaks. For instance, the GeV peak present in GRB 080916C coincides with the second bright peak in the GBM LC, suggesting that GeV emission is the spectral extension of MeV emission to higher energies (Zhang et al. 2011). However, other bursts such as GRB 090510 do not exhibit these remarkable coincidences between peaks (see Figure 8, Zhang et al. 2011). Finally, the author concluded that for the LAT/GBM bursts analyzed (all except GRBs 090902B and 090510), the LAT and GBM photons consistently belong to the same spectral component, suggesting a possible common origin.

We thank the anonymous referee for a critical reading of the paper and valuable suggestions that helped improve the quality and clarity of this work. We thank Peter Meszaros, Anatoly Spitkovsky, Dimitrios Giannios and Fabio de Colle for useful discussions. This work was supported by the project PAPIIT IG100414. PV gratefully acknowledges Fermi grant NNM11AA01A and partial support from the OTKA NN 111016 grant.

APPENDIX

The quantities are given by

$$A_{\text{syn}} \approx \frac{m_e^2}{32/3} \frac{\alpha_{\text{eff}}^2}{\beta
} \frac{m^2}{\beta^2} \left(\frac{3/2}{\beta^2} \frac{\epsilon_{\text{B}}^2}{\beta^2} \right) \left(1 + \frac{1}{\beta^2} \right) \epsilon_{\text{B}} / D^{-2} E^{-2},$$

$$A_{\text{ph}} \approx \frac{m_e^2}{32/4} \frac{\alpha_{\text{eff}}^2}{\beta
} \frac{m^2}{\beta^2} \left(\frac{3/2}{\beta^2} \frac{\epsilon_{\text{B}}^2}{\beta^2} \right) \left(1 + \frac{1}{\beta^2} \right) \epsilon_{\text{B}} / D^{-2} E^{-2},$$

$$A_{\text{al}} \approx \frac{m_e^2}{32/5} \frac{\alpha_{\text{eff}}^2}{\beta
} \frac{m^2}{\beta^2} \left(\frac{3/2}{\beta^2} \frac{\epsilon_{\text{B}}^2}{\beta^2} \right) \left(1 + \frac{1}{\beta^2} \right) \epsilon_{\text{B}} / D^{-2} E^{-2},$$
