We present measurements of fluid particle accelerations in turbulent water flows between counter-rotating disks using three-dimensional Lagrangian particle tracking. By simultaneously following multiple particles with sub-Kolmogorov-time-scale temporal resolution, we measured the spatial correlation of fluid particle acceleration at Taylor microscale Reynolds numbers between 200 and 690. We also obtained indirect, non-intrusive measurements of the Eulerian pressure structure functions by integrating the acceleration correlations. Our experimental data provide strong support to the theoretical predictions of the acceleration correlations and the pressure structure function in isotropic high Reynolds number turbulence by Obukhov and Yaglom in 1951. The measured pressure structure functions display K41 scaling in the inertial range.

PACS numbers: 47.27.Gs, 47.27.Jv, 47.80.Fg

Fluid particle acceleration is an important quantity in turbulent flows [1]. For example, it plays a significant role in the formation of cloud droplets in the atmosphere [2]. In recent years, advances in the study of the statistics of acceleration have been made through the development of Lagrangian experimental techniques [3, 4, 5] and the use of direct numerical simulations (see, e.g., Refs. [6, 7]). Using silicon-strip detectors operating at recording frequencies as high as 70 kHz, La Porta and co-workers [4, 5] were able to follow passive tracer particles in a water flow at Taylor microscale Reynolds numbers up to $R_{\Lambda} \sim 10^3$. Fluid particle accelerations were obtained from the trajectories of the tracer particles. Their results revealed the highly intermittent nature of acceleration, and also showed the necessity of sub-$\tau_6$ temporal resolution for obtaining accurate acceleration measurements, where $\tau_6$ is the Kolmogorov time scale, the smallest time scale in turbulence. In later studies, the same technique was used to investigate the Lagrangian properties of acceleration following a fluid particle [8, 9]. Due to the one-dimensional nature of the silicon-strip detectors, however, only one fluid particle could be followed at a time. Consequently, the spatial properties of acceleration were not explored in these previous studies. In other particle tracking experiments, digital cameras were used to record the motion of tracer particles and multi-particle statistics were obtained [10, 11]. These experiments, however, were limited to flows with small Reynolds numbers because of the slower recording frequency of the cameras. Very recently, advances in CMOS camera technology have provided the opportunity of measuring the acceleration of multiple tracer particles simultaneously in high Reynolds number turbulent flows [12]. In this Letter, we present the first direct experimental measurement of the spatial correlations of acceleration in turbulent flows with $200 \leq R_{\Lambda} \leq 690$.

Another important quantity in high Reynolds number turbulence that is not clearly understood is pressure. It has been shown that the clustering of inertial particles in turbulence is related to the scaling properties of the pressure field [13]. It is, however, extremely difficult to measure pressure in turbulent flows non-intrusively. Ould-Rouis et al. [14] reported that, in the inertial range, the pressure structure functions computed from the fourth order longitudinal velocity structure functions scale as predicted by Kolmogorov’s K41 theory [15, 16, 17] when the Reynolds number is moderately high ($R_{\Lambda} \geq 230$). However, Hill & Boratav [18] argued that very large Reynolds numbers are needed to observe K41 scaling and the assumptions made by Ould-Rouis et al. result in large uncertainties in the calculated pressure structure function. Pressure spectra obtained from numerical simulations [19] suggested that the K41 pressure spectrum can only be observed at $R_{\Lambda} > 600$. The spectra obtained from direct pressure measurements in turbulent jets by Tsuji & Ishihara [20] seem to support this conclusion. In this experiment, however, the effect of Taylor’s frozen flow hypothesis on the pressure spectra has not been fully evaluated.

In high Reynolds number turbulence, the acceleration is mostly determined by the pressure gradient, and the viscous term may be ignored [21]. Under this assumption, there exist analytical relations between the spatial correlations of acceleration and the Eulerian pressure structure function [16, 17]. By exploiting such relations, we obtain an indirect but non-intrusive measurement of the pressure structure functions in high Reynolds number turbulence. Our experimental results strongly support the theoretical predictions of Obukhov & Yaglom based on K41.
In homogeneous, isotropic turbulence, the Eulerian pressure structure function depends only on the separation distance, i.e., $\Pi(r) \equiv \langle [p(x) - p(x + r)]^2 \rangle = \Pi(r)$. For high Reynolds number flows, the fluid acceleration is dominated by the local pressure gradient. Hence,

$$R_{ij}(r) = \frac{1}{\rho^2} \left( \frac{\partial p}{\partial x_i} \right)_x \left( \frac{\partial p}{\partial x_j} \right)_{x+r}.$$ (1)

Using the relation between the correlation of pressure gradients and the pressure structure function in homogeneous turbulence, the acceleration correlation can be related to the pressure structure function as $[16]$

$$R_{ij}(r) = \frac{1}{2\rho^2} \frac{\partial^2 \Pi(r)}{\partial r_i \partial r_j}.$$ (2)

In homogeneous, isotropic turbulence, this reduces to

$$R_{LL}(r) = \frac{1}{2\rho^2} \frac{d^2 \Pi(r)}{dr^2}, \quad R_{NN}(r) = \frac{1}{2\rho^2} \frac{d \Pi(r)}{dr},$$ (3)

where $R_{LL}(r)$ and $R_{NN}(r)$ are the longitudinal and transverse acceleration correlations, respectively. Therefore, once either $\Pi(r)$ or $R_{ij}(r)$ is determined, the other can also be obtained. It should be emphasized that Eqs. (3) hold in homogeneous, isotropic turbulence at high Reynolds numbers. The only simplification invoked in deriving these equations is the neglect of a viscous contribution to acceleration.

In their work, Obukhov & Yaglom further assumed, as first proposed by Millionshchikov [22] and Heisenberg [23], that the components of the velocity gradient are drawn from a multi-dimensional Gaussian distribution. Under this hypothesis, the pressure structure function in homogeneous, isotropic turbulence satisfies

$$\frac{d^4 \Pi(r)}{dr^4} + \frac{4}{r} \frac{d^3 \Pi(r)}{dr^3} = -\rho^2 \Phi(r),$$ (4)

where $\Phi(r)$ can be written in terms of the derivatives of the longitudinal velocity structure function $D_{LL}(r)$:

$$\Phi(r) \equiv D_{LL}' \left( 4 D_{LL}'' + \frac{20 D_{LL}'''}{r} + \frac{6 D_{LL}'''}{r^2} \right) + 4 \left( D_{LL}' \right)^2.$$ (5)

An equation for $D_{LL}$ can be obtained from the Kármán-Howarth equation [24] as

$$6\nu \frac{d D_{LL}}{dr} + |S| D_{LL}(r)^3/2 = 4 \frac{4}{5} r,$$ (6)

where $S$ is the structure function skewness [25]. Obukhov & Yaglom [16] assumed that $S$ is constant for all separations $r$, and so it can be related to the Kolmogorov constant $C_2$ for the structure function $D_{LL}(r)$ as $|S| = (4/5)C_2^{-3/2}$ and the value of $C_2 = 2.13$ is well known from experiments [26]. Upon solving Eq. (1) numerically for $D_{LL}(r)$, Eq. (4) is solved for $\Pi(r)$ using Green's functions. The acceleration correlations $R_{LL}(r)$ and $R_{NN}(r)$ are then obtained from Eqs. (3).

We carried out three-dimensional Lagrangian Particle Tracking experiments in a von Kármán water flow between counter rotating disks. Our experimental technique and particle-tracking algorithm have been described in detail previously [12, 27, 28]. Here, we report measurements from four experiments with Taylor microscale Reynolds numbers ranging from 200 to 690. The relevant parameters of the flow and the experiments are shown in Table I. All measurements were done in the same apparatus described in Ref. [12], except for the $R_\lambda = 460$ experiment, which was carried out in a new apparatus with a similar geometry but a different disk propeller. As a result, the integral length scale $L$ of this experiment is markedly different from $L$ in the other three. In the $R_\lambda = 460$ experiment, we used the Phantom v7.3 cameras from Vision Research Inc., which are capable of recording at 37,000 frames per second at a resolution of $256 \times 256$ pixels, nearly a 40% increase in frame rate compared to the v7.2 cameras used in the other experiments. Therefore, the $R_\lambda = 460$ experiment has the highest temporal resolution among the four experiments reported here.

We have shown before that the probability density functions (PDFs) of acceleration measured in the $R_\lambda = 690$ experiment agree well with previous measurements using silicon-strip detectors [12]. Figure I compares the acceleration PDF measured in the $R_\lambda = 460$ experiment with the PDF measured in Ref. [29] at $R_\lambda = 690$ using...
TABLE I: Parameters of the experiments. $u'$ is the root-mean-square velocity, $\varepsilon$ is the turbulent energy dissipation rate per unit mass. $L \equiv u'^3/\varepsilon$ is the integral length scale. $\eta$ and $\tau_\eta$ are the Kolmogorov length and time scales, respectively. $N_f$ is the frame rate of the cameras, in frames per second. $N_s$ is the number of acceleration measurements.

| $R_\lambda$ | $u'$ (m/s) | $\varepsilon$ (m$^2$/s$^3$) | $L$ (mm) | $\eta$ (µm) | $\tau_\eta$ (ns) | $N_f$ (frames/τ$\eta$) | meas. vol. (µm$^3$) | $\Delta x$ (µm/pix) | $N_s$ |
|------------|------------|-----------------------------|---------|------------|----------------|-----------------------|-------------------|----------------|------|
| 200        | 0.035      | $7.2 \times 10^{-4}$        | 61      | 194        | 37            | 37                | 100×100×100       | 80               | 2.5×10$^7$ |
| 350        | 0.11       | $2.0 \times 10^{-2}$        | 67      | 84         | 7.0           | 35                 | 300×300×300       | 50               | 9.0×10$^7$ |
| 460        | 0.25       | 0.28                        | 56      | 43         | 1.9           | 69                 | 240×240×240       | 40               | 3.3×10$^7$ |
| 690        | 0.42       | 1.2                         | 62      | 30         | 0.90          | 24                 | 670×670×670       | 80               | 8.5×10$^7$ |

The agreement between the two measurements, however, suggests that using multiple cameras to determine the 3D particle position results in better accuracy than the one-dimensional silicon-strip detector measurements.

In Figure 2, we compare the longitudinal and transverse acceleration correlation coefficients measured at different Reynolds numbers with the theoretical predictions by Obukhov & Yaglom [16], as obtained from Eqs. (3). It can be seen from Fig. 2(a) that the predictions agree well with the experimental data. As the Reynolds number increases, the agreement between the predictions and the measurements increases. This is not surprising given that the viscous contribution to acceleration is neglected in the theoretical predictions.

At large separations, the predicted acceleration correlations approach simple asymptotic scaling laws [16]:

$$R_{LL}(r) \sim \frac{2C_2^2}{9} \varepsilon^{3/2} \nu^{-1/2} (r/\eta)^{-2/3}, \quad (7)$$

$$R_{NN}(r) \sim \frac{2C_2^2}{3} \varepsilon^{3/2} \nu^{-1/2} (r/\eta)^{-2/3}. \quad (8)$$

Figure 2(b) compares Eqs. (7) and (8) with experimental data. There are small but appreciable discrepancies between the prediction and the measurements, which may be caused by the finite measurement volume and/or may reflect the need for still larger separations to see the asymptotic behavior. Another possible reason for the discrepancies may be caused by the finite measurement volume and/or may reflect the need for still larger separations to see the asymptotic behavior. Another possible reason for the discrepancies is the theoretical predictions that the viscous contribution to acceleration is neglected in the theoretical predictions.
crepancy is that our flows are not isotropic. We observe anisotropy in acceleration even at the largest Reynolds number investigated, although the anisotropy decreases with increasing Reynolds number.

Recently, Hill [31] proposed a refined theory for the acceleration correlations at small separations where the contribution from viscous forces is not neglected. Due to the limited spatial resolution in our experiment, however, our measurements cannot be used to test that theory.

We obtain the pressure structure function by numerically integrating the equation for $R_{NN}(r)$ in [3] with experimentally measured transverse acceleration correlations. As already mentioned before, this equation holds in homogeneous, isotropic turbulence at high Reynolds numbers where the viscous contribution vanishes.

In Fig. 3 we compare the prediction by Obukhov and Yaglom [Eqs. (4) to (6)] with measurements obtained from the acceleration correlations. We plot the normalized pressure structure function $D_p(r) \equiv \Pi(r)/\rho^2 \nu \varepsilon$. The measured data and the predictions are in good agreement over the range of separations accessible in the experiments. K41 inertial range scaling can be obtained from the limiting case of $r \gg \eta$ in the prediction of $\Pi(r)$, yielding $D_p(r) \sim (r/\eta)^{4/3}$, which is also plotted in Fig. 3. This scaling law is close to the experimental data in the inertial range. The small deviations may be an indication of intermittency. The finite Reynolds numbers and finite measurement volume effects could also contribute to the deviation in the scaling exponent.

Recently, Bec et al. [13] reported a $r^{2/3}$ inertial range scaling for the pressure structure functions from DNS data up to $R_\lambda = 185$. They also postulated that the $r^{2/3}$ scaling would persist at low Reynolds numbers and the K41 scaling might be observed only when $R_\lambda \geq 600$. The $r^{2/3}$ scaling law is shown in Fig. 3 for reference. As can be seen, all experimental data are much closer to the K41 scaling rather than $r^{2/3}$ scaling, and there is no appreciable change of slope over the range of $200 \leq R_\lambda \leq 690$. The discrepancies between experimental observation and numerical simulation remain to be investigated.

Finally, let us note that the extent of the nominal inertial range measured from the spectrum or from structure functions can be very different, as has been shown for the case of Lagrangian velocity [22]. This subtlety could account for the difference between our experimental results and previous investigations, in which the pressure spectra were studied.

In summary, we simultaneously followed the trajectories of multiple passive tracer particles in turbulent water flows with Reynolds number in the range $200 \leq R_\lambda \leq 690$. The accuracy of the accelerations measured from the trajectories is comparable to previous single-particle measurements. We obtained spatial acceleration correlations from the multi-particle measurement and used the measured acceleration correlations to compute pressure structure functions from a relation that holds at high Reynolds numbers. We compared the measurements with theoretical predictions by Obukhov & Yaglom [16] and found that the predictions of both the acceleration correlations and the pressure structure functions are in good agreement with the experimental data. We also observed K41 inertial range scaling in the measured pressure structure functions over the range of Reynolds numbers investigated.

We thank Jérémie Bec for helpful discussions and Jakob Mann for bringing Ref. [16] to our attention. This work was supported by the NSF under Grants PHY-9988755 and PHY-0216406 and by the Max Planck Society.
