ABSTRACT
Stellar models rely on a number of free parameters. High-quality observations of eclipsing binary stars observed by Kepler offer a great opportunity to calibrate model parameters for evolved stars. Our study focuses on six Kepler red giants with the goal of calibrating the mixing-length parameter of convection as well as the asteroseismic surface term in models. We introduce a new method to improve the identification of oscillation modes which exploits theoretical frequencies to guide the mode identification (’peak-bagging’) stage of the data analysis. Our results indicate that the convective mixing-length parameter ($\alpha$) is $\approx 14\%$ larger for red giants than for the Sun, in agreement with recent results from modelling the APOGEE stars. We found that the asteroseismic surface term (i.e. the frequency offset between the observed and predicted modes) correlates with stellar parameters ($T_{\text{eff}}$, $\log g$) and the mixing-length parameter. This frequency offset generally decreases as giants evolve. The two coefficients $a_{-1}$ and $a_{3}$ for the inverse and cubic terms that have been used to describe the surface term correction are found to correlate linearly. The effect of the surface term is also seen in the p-g mixed modes, however, established methods for correcting the effect are not able to properly correct the g-dominated modes in late evolved stars.

Key words: star: evolution – star: oscillation

1 INTRODUCTION
Stellar models describe internal structures and evolutionary states of stars. The basic equations were established decades ago and are able to reproduce the general features of stars. However, current theoretical models are commonly working with a number of free parameters. The atmospheres of stars can be measured by photometry and spectroscopy, while the stellar masses, ages, and internal structures are mostly provided by models. Thus, both observational and theoretical calibrations are required for a proper understanding of stars. Free parameters, however, undermine the reliability of theoretical models and increase the true uncertainties of modelling results. These parameters need calibrations for different types of stars, but unfortunately, theoretical tests beyond the solar case are sparse, especially for red giants.

Among Kepler red giants, a few have been identified as eclipsing binaries (EBs). Combining eclipses with radial velocities from spectra allows masses and radii of both companions of the binary to be determined from dynamical modelling (Frandsen et al. 2013; Gaulme et al. 2016), providing the key constraints for stars. The structures and evolutionary histories of detached companions are similar to that of single stars, and hence they are a good population for testing the model parameters. Red giants have helium cores and burn hydrogen in a surrounding shell. Characteristics...
of the core decide the temperature of the H-burning shell and hence determine the total luminosity. Tight constraints on the physics of the models for red giants would require measurements of the core (Lagarde et al. 2015). Modelling the red giants with precise measurements of the solar-like oscillations by Kepler can provide powerful constraints on stellar properties (Pérez Hernández et al. 2016; Jiang et al. 2011). The acoustic modes mainly probe the envelope, but the mixed modes caused by the p and g mode coupling probe the properties of the core (Bedding et al. 2011; Mosser et al. 2014; Lagarde et al. 2016). Thus, red giants in binary systems with well-defined oscillating patterns, offer an important opportunity to test free parameters in stellar models.

Low-mass dwarfs and red giants have convective envelopes, where the energy transport is dominated by convection. Simulating the real dynamic process for the whole region comes with great difficulties in computation, hence a mixing-length approximation is adopted in stellar evolution models. The basic idea of the mixing-length theory is to define a characteristic length for a fluid parcel, over which it maintains its original properties before mixing with the surrounding fluid. The mixing-length parameter ($\alpha \equiv l/H_p$) characterizes this length in the stellar model, where $l$ is the mixing length, and $H_p$ is the pressure scale height. For low-mass red giants, the value of $\alpha$ mainly correlates with the total radius and the structure of the envelope. With the independent measurements of masses and radii, as well as the internal structures probed by asteroseismology, this parameter could be constrained properly by seismic red giants in eclipsing binaries.

The surface term is the systematic offset of individual frequencies between models and observations and arises from poor modelling of the near-surface layers (Christensen-Dalsgaard et al. 1988, 1996; Christensen-Dalsgaard & Thompson 1997). Roxburgh & Vorontsov (2003) suggested using the ratio of small to large separations to fit models to observations. The advantage of this method is avoiding the uncertainty of the outer layers since the ratio is mainly determined by the interior structure. Kjeldsen et al. (2008) fitted oscillation frequencies of the Sun and three well determined by the interior structure. Kjeldsen et al. (2008) characterized this length in the stellar model, where $l$ is the mixing length, and $H_p$ is the pressure scale height. For low-mass red giants, the value of $\alpha$ mainly correlates with the total radius and the structure of the envelope. With the independent measurements of masses and radii, as well as the internal structures probed by asteroseismology, this parameter could be constrained properly by seismic red giants in eclipsing binaries.

The surface term is the systematic offset of individual frequencies between models and observations and arises from poor modelling of the near-surface layers (Christensen-Dalsgaard et al. 1988, 1996; Christensen-Dalsgaard & Thompson 1997). Roxburgh & Vorontsov (2003) suggested using the ratio of small to large separations to fit models to observations. The advantage of this method is avoiding the uncertainty of the outer layers since the ratio is mainly determined by the interior structure. Kjeldsen et al. (2008) fitted oscillation frequencies of the Sun and three well identified sun-like dwarfs with the surface term corrected by a power law. The approach showed good agreement and has been widely applied to other stars. A later update of the surface correction formulas given by Ball & Gizon (2014) took mode inertia into account and modelled the surface effects by terms proportional to $\nu^{-1}/I$ and $\nu^2/I$ based on the discussion of potential asymptotic forms for frequency shifts by Gough (1990). Sonoi et al. (2015) further applied 3D hydrodynamical simulations to derive expressions for the surface correction. The surface term is strongly correlated to surface properties, such as effective temperature and surface gravity. It also relates to model parameters, especially the mixing length parameter, which determine the structure of the envelope. For this reason, the surface term calibrated to the Sun does not apply directly to other stars and all current methods introduce free parameters because of the uncertainty of the surface layers. The seismic red giants in eclipsing binaries, as mentioned above, provide us some of the best constrained stars apart from the Sun and they can be the ideal sample for studying the surface term in evolved stars.

In this work, we selected six Kepler red giants in eclipsing binaries with detectable solar-like oscillations from Gaulme et al. (2016) for calibrating the mixing-length parameter and the surface term. We used four-years of Kepler data to get seismic frequencies and then generate theoretical models for each star. All available observed constraints, namely, mass, radius, atmospheric parameters and stellar oscillations, are used for the calibrations.

2 KEPLER EB TARGETS

2.1 Target Selection

In this work we used red giants in detached eclipsing binaries from Gaulme et al. (2016), who used photometric data from the Kepler mission and spectra obtained by the 3.5-m ARC telescope at APO (ARCES) and the Sloan Digital Sky Survey (APOGEE) for measuring eclipses and radial velocities of the binaries. These binary systems each comprise one dwarf and one giant ranging from 1.0 to 1.6 $M_\odot$. The giants are slightly more massive than their dwarf companions. The companions are sufficiently distant for them to evolve independently, because the separations are roughly 10 to 20 times the radii of the primary stars. From the sample, we selected six red giants showing high S/N solar-like oscillations as our targets. Fundamental stellar parameters of the selected stars are summarised in Table 1. Obvious systematic differences can be seen in the effective temperatures and metallicities between ARCES and APOGEE. Because both observations were based on high-resolution spectra, we used their average $T_{\text{eff}}$ and [Fe/H] and the mean uncertainties of the two parameters in this work, which were also given in Table 1.

2.2 Stellar Oscillation and Data Analysis

We used Kepler long-cadence data and the SYD pipeline (Huber et al. 2009) to extract solar-like oscillations of the six red giants. The reduction steps for preparing light curves include cutting out safe-modes, correcting the jumps, removing long-period variation by a high-pass filter and the eclipses using the orbital periods in Gaulme et al. (2016). The top panel in Figure 1 includes the normalised light curves of KIC 9970396 after the reduction. We then calculated power spectra, estimated the region of power excess, fitted to and corrected for the background on power spectra. The bottom panel in Figure 1 shows the background-corrected power spectra of KIC 9970396. It should be noted that the unit S/N indicates the ratio between the power density of stellar oscillations and the power density of the background.

Because the long-term variations (from eclipses, instrumental drifts, and stellar spots) and the granulation background had been removed from the power spectra we used to study stellar oscillation, the noise is mainly white. The power spectrum of white noise follows a chisquare distribution with two degrees of freedom in the frequency domain (Chaplin et al. 2002). We used the frequency bins from 5 to 290 $\mu$Hz to calculate the probability density function (PDF) of the power density, which can be seen in the bottom right panel in Figure 1. The larger the power excess over the white noise distribution, the more likely that power comes from
the mode frequency is approximated by
\[ \nu_{nl} = \nu + \frac{l}{2} + \epsilon \]
where \( n \) is the radial order, \( \epsilon \) is a parameter related to stellar surface features, and \( \delta_{nl} \) is the small separation. The large separation for the stars were calculated by the SYD pipeline. And the small separation are roughly measured by hand in the échelle diagram. We got the first guesses of the modes for \( l = 0 \) and 2 by this function. The \( l = 1 \) modes couple to g-modes more strongly, and hence multiple modes were seen for a given order \( n \) in the power spectrum. We measured the median frequency of the multiple \( l = 1 \) peaks as the initial guess for the most-p-like mode. For a proper estimation of individual modes, we applied the same Monte-Carlo simulations as mentioned above and generated 1,000 simulated power spectra for each star. The least-squares method was then used to fit the individual mode in each simulated power spectrum. A Lorentzian function was used for fitting the most-p-like modes for \( l = 1 \), we used a Gaussian function to fit the shape of the mode. The Lorentzian/Gaussian function had three free parameters, namely, the centre, the amplitude, and the width. We fixed the baseline as 1.0, which is the median value of the noise in the unit of S/N. The frequency range for fitting \( l = 0 \) and 2 modes was set as \( \pm 0.6\delta
u_{\text{max}} \) centred at the initial guesses. The fitting region for \( l = 1 \) modes varied for different cases and was determined through visual inspection. We also adopted the \( P_{\text{signal}} \) as the weight of each frequency bin when calculating the least-squares of a fitting. First, signal deserves larger weight than noise. Secondly, this fitting method could get reasonable width for the radial modes with low S/N. For some cases when the power excess of a mode shows multiple peaks in the power spectra (e.g. the \( l = 0 \) mode shown in the left bottom panel in Figure 2), the least-squares method without taking account the weight may fit one of these peaks instead of fitting all of them, giving an unrealistically narrow width for the mode.

After the fitting process above, each mode were mea-

\end{itemize}
Figure 1. Top: the normalised flux of the Kepler light curve of KIC 9970396. Bottom left: background-corrected power spectrum of solar-like oscillations of KIC 9970396 generated by SYD pipeline (Huber et al. 2009). Colour code indicates the probability of each frequency bin being signal ($P_{\text{signal}}$). Bottom right: the probability distribution of the power density.

We adopted the input physics of the calibrated solar model of the 'test_suite' case except for the atomic diffusion. In summary, the solar chemical mixture ($[(Z/X)_{\odot} = 0.0229]$) provided by Grevesse & Sauval (1998) was adopted because solar models calibrated with this mixture (Bi et al. 2011) fit the internal structures from helioseismic inversion better than those with more recent measurements (Asplund et al. 2005, 2009). To determine initial abundances of hydrogen and helium ($X_{\text{init}}$ and $Y_{\text{init}}$) for a given content of heavy elements ($Z_{\text{init}}$), we used the following formula:

$$Y_0 = 0.249$$  

$$Y_{\text{init}} = Y_0 + \frac{\Delta Y}{\Delta Z} Z_{\text{init}}$$  

$$X + Y + Z = 1.$$  

The primordial helium abundance ($Y_0$) is determined by Planck Collaboration et al. (2016) using the Planck power spectra, Planck lensing, and some external data such as baryonic acoustic oscillations. The ratio $\Delta Y/\Delta Z$ in Eq. 3 can be computed by the initial abundances of helium and heavy elements of the Sun. We adopted the $Y_{\odot,\text{init}}$ and $Z_{\odot,\text{init}}$ of the calibrated solar model given by Paxton et al. (2011), which are 0.2744 and 0.0191 (different from the present-day abundances of 0.243 and 0.0170), and hence the ratio $\Delta Y/\Delta Z$ is 1.33. The MESA $\rho$-T tables are based on the 2005 update of OPAL EOS tables (Rogers & Nayfonov 2002) and opal opacity for the solar composition of Grevesse & Sauval (1998) supplemented by the low-temperature opacity (Ferguson et al. 2002) are used. The mixing length the-
ory of convection is implemented, and $\alpha \equiv l/H_p$ is the mixing-length parameter for modulating convection. Convective overshooting is set as described by Paxton et al. (2011, Section 5.2) and the overshooting mixing coefficient was

$$D_{OV} = D_{conv,0} \exp\left(-\frac{2z}{fH_p}\right),$$

where $D_{conv,0}$ is the mixing length theory derived diffusion coefficient at a user-defined location near the Schwarzschild boundary, $z$ is the distance in the radiation layer away from the location, and $f$ is a free parameter to change the overshooting scale. The photosphere tables is used as the set of boundary conditions for model atmosphere.

### 3.2 Stellar Oscillation Model

The Aarhus Adiabatic Oscillation Package (ADIPLS) is a simple and efficient tool for the computation of adiabatic oscillation frequencies and eigenfunctions for general stellar models (Christensen-Dalsgaard 2008, 2011). It was used for computing all theoretical seismic modes in this work. Input parameters for ADIPLS follow the suite for red giants included in the package. It should note that structural models generated by MESA (Format FGONG, www.astro.up.pt/corot/ntools/docs/Corot_ESTA_Files.pdf) are redistributed for calculating seismic mixed modes. The number of structural shells ($N_{Grid}$) after redistribution could slightly change the results of frequencies. We tested some fitting models with $N_{Grid}$ from ~2,000 to ~20,000.

And computed frequencies become stable when $N_{Grid}$ is greater than ~6,000. For all the calculations with ADIPLS, we finally redistributed structural models into 9601 shells.

### 3.3 The Surface Correction

We used the combined expression and the method described by Ball & Gizon (2014) for correcting the surface term. Based on the discussion of potential asymptotic forms for frequency shifts (Gough 1990), the correction formula is a combination of inverse and cubic terms:

$$\delta \nu = (a_{-1}(\nu/\nu_{ac})^{-1} + a_3(\nu/\nu_{ac})^3)/I,$$

where $a_{-1}$ and $a_3$ are coefficients adjusted to obtain the best frequency correction $(\delta \nu)$. The method to determine these two coefficients for given set of observed and model frequencies was described by Ball & Gizon (2014). According to the frequency offsets found on the Sun and other well studied solar-like stars (Ball & Gizon 2014; Kjeldsen et al. 2008), $\delta \nu$ increases with frequency. In Eq. 6, the surface term is also modulated by the normalised mode inertia, $I$. The description of $I$ can be found in Aerts et al. (2010, Eq. (3.140)). To avoid confusion, we note that the output results from ADIPLS (ADIPLS notes, Eq. 4.3a and 4.3b) in the current version is $I/4\pi$. $\nu_{ac}$ in Eq. 6 is the acoustic cut-off frequency, which is derived from the scaling relation (Brown et al. 1991)

$$\frac{\nu_{ac}}{\nu_{ac,\odot}} \approx \frac{g}{g_{\odot}} \left(\frac{T_{eff,\odot}}{T_{eff,\odot}}\right)^{-1/2}.$$

Here we take $\nu_{ac,\odot} = 5000 \mu Hz$ from Ball & Gizon (2014). Solar references of effective temperature and surface gravity are log $g_{\odot} = 4.44$ and $T_{eff,\odot} = 5777 K$ (Cox 2000).

### 4 THEORETICAL COMPUTATIONS AND RESULTS

#### 4.1 Grid Computation

The free input parameters for the grid computation include mass ($M$), initial abundance of heavy elements ($Z_{init}$) converted from metallicity ([Fe/H]), initial abundances of hydrogen and helium ($X_{init}$ and $Y_{init}$) which are computed by Eq. 2-4 for a given $Z_{init}$, the mixing-length parameter ($\alpha$), and the overshooting parameter ($f_{ov}$). We used the masses and their 1-σ uncertainties given by Gaulme et al. (2016) as the range of input $M$. The input range of [Fe/H] was estimated by both individual measurements of ARCES and APOGEE. The lower limit was calculated with the lower observed [Fe/H] minus its 1-σ uncertainty, and the upper limit was got from the higher observed [Fe/H] plus its 1-σ uncertainty. For instance, the metallicities of KIC 9970396 given by ARCES and APOGEE are -0.23±0.03 and -0.18±0.07, and hence the input range of [Fe/H] for this star is from -0.26 to -0.11. The grid of input $M$ and [Fe/H] were spaced by 0.01$M_{\odot}$ and 0.05 dex, respectively. We tested the mixing-length parameter ($\alpha$) in a wide range around the solar value (Paxton et al. 2011, $\alpha_{\odot} = 1.92$). The grid of $\alpha$ is from 1.72 to 2.52 with a step of 0.1. The overshooting parameter $f_{ov}$ was either 0.008, 0.012, 0.016 or 0.020, where the upper limit for this parameter (0.020) was estimated by Magal et al. (2010). We used the MESA asteroseismic ‘grid search’ function

![Figure 2](image.png)
to generate the grid. In this way, MESA saves structural models that fit observed constraints for further analysis. We used four global observables of each star as the constraints of the ‘grid search’, namely, the average effective temperature and metallicity from spectra, as well as the surface gravity and radius from the binary studies. We set a cut-off value of total \( \chi^2 \) as 8.0 for selecting MESA models. (For a \( \chi^2 \) distribution with 4 degrees of freedom, the probability for \( \chi^2 \) smaller than 8 is 0.91.) A summary of the grid computation with MESA can be found in Table 2. ADIPLS was then implemented for calculating radial \((l = 0)\) and non-radial oscillation modes \((l = 1 \text{ and } 2)\).

4.2 Reordering of Theoretical Mixed Modes

Before discussing the subsequent fitting progress, we address one problem that arises with the current way of applying the surface correction in evolved stars: theoretical mixed modes could lose their original order after their surface terms are corrected. We took the model of KIC 7037405 as an example. Fig. 3 shows the mixed modes for \( l = 1 \) and 2 in a single order of this model. Theoretical mode inertia are plotted against frequencies before and after the surface correction. Due to the quick change of inertia, p-dominated modes (with the lower inertia) get much larger corrections than their g-dominated neighbours. And the modes obtain a new order after the correction. Similar reordering appears in theoretical \( l = 1 \) mixed modes of KIC 5786154, KIC 7037405, and KIC 9940226 and in the \( l = 2 \) modes of all six targets. The re-ordering happens because the surface corrections for the mixed modes differ by more than the separation between consecutive modes. The g-like modes are less changed by the surface properties than p-like modes due to their large mode inertia. And hence we do not expect a strong surface term for them. However, one thing worth to note is that theoretical mixed modes are solved as the coupling results of p and g modes. If the surface term of the p-mode is not being corrected before calculating the coupling, the mixed modes will also be affected.

A proper way to test this issue could be correcting the acoustic wave before calculating the mixed modes. However, no option is available in the seismic code to do this job. Instead, we changed the structure in the near-surface layers of the input model of ADIPLS. This only alters the acoustic wave, but not the gravity modes because they travel inside the core. Modifying the adiabatic exponent \( (\Gamma_1 = (dlnp/dlnp)_{adi}) \) in the near-surface layers is a simple way to modulate the acoustic resonance. However, it should be noted that the structural model after this modification is no longer self-consistent. For the case of the Sun, the surface term starts from 1Mm below its surface where \( T = T_{CH} \). The depth of this region is roughly 0.15% of the total solar radius. Hence we only changed \( \Gamma_1 \) in layers that are 0.15% of the total radius below the surface. As shown in the top graph of Figure 4, we gradually increased \( \Gamma_1 \) in the region from 0.9985 \( R \) to the surface. The fractional increase at given depth followed a Gaussian function (blue dotted line). The centre of the Gaussian profile is right on the top layer. And its amplitude and width are 0.3 and 0.0005\( R \), respectively. The mixed modes for \( l = 1 \) and 2 calculated with the models before and after modifying the surface-corrected \( \Gamma_1 \) are also given in the middle and bottom panels. It can be found that the change in surface layers affects the most p-like modes. Shifted p modes then change the frequency ranges where p-g coupling happens. Thus, the surface term also affects the mixed modes in an indirectly way.

Modifying the stellar structure seems to be a way to repair the indirect effects of the surface term on mixed modes. However, it comes with difficulties in rebuilding the equilibrium of the model. We hence still adopted the correcting formula (Eq. 6) to correct model frequencies. To avoid the influence when using it in the following fitting procedures, we checked the model frequencies for all six stars. Hence only the most-p-like modes are considered for these cases. The \( l = 1 \) mixed modes of the other three stars (KIC4663263, KIC8410637, and KIC9970396) have large enough period spacing to overcome the surface effect without mode order swapping and were used for the following studies. Based on the models of six red giants, \( \nu_{max} \) greater than \( \sim 40 \mu Hz \) tends to be a safe cut for stars whose mixed modes for \( l = 1 \) can be adopted. We will mention the identification of observed individual mixed modes for these stars below.

4.3 Identification of Individual Mixed Modes

Peak-bagging of individual mixed modes for red giants is complicated by rotational splitting, granulation background, and random noise. On the other side, the theoretical models provide precise oscillation frequencies of mixed modes for every degree and order, which can be a guide to peak-bagging.

We firstly found theoretical models which fit the observed modes for \( l = 0 \) and 2 (the model with the highest 10% likelihood). These models then guided us to identify \( l \)
model was firstly constrained by the modes for peak-bagging process of mixed modes for KIC9970396. The = 1 modes. One example, as given in Fig. 5, illustrates the modification. Bottom: mixed modes for = 1 modes. One example, as given in Fig. 5, illustrates the modification. Bottom: mixed modes for = 1 (filled symbols), such as the three peaks from 66.7 to 67.2 μHz. All model frequencies were then plotted on the power spectrum (open triangles), suggesting more potential modes like the one at 66.4 μHz, and two at 67.4 and 67.7 μHz. It should be noted that the power of these modes is still significant compared with the background noise level. The method we use for getting the frequencies and uncertainties of individual mixed modes are as follow. For a potential mode based on the visual inspection, we flagged the observed peaks with $P_{\text{signal}} > 0.5$ around the theoretical predictions. The median value of these peaks was adopted as the frequency of this mode. And the difference between the median value and the highest/lowest frequency was measured as the uncertainty. The blue error bars in Figure 1 represent all of the identified modes and their uncertainties. We also tried to identify the g-dominated modes for $l = 2$ (on the left side). However, no significant mode has been found because of their large inertia. All the identified modes of KIC 9970396 are listed in Table 3. The power spectra and tables of all six stars can be found in the Appendix.

4.4 Calibrating the Model Parameters

We used a Bayesian method to estimate the mixing-length parameter ($\alpha$) and the two coefficients for surface correction ($a_1$ and $a_3$). The agreement between models and observations was first examined by a likelihood function. The observed data for these stars can be divided into three parts. The mass, radius, and atmospheres provide global features; p and the most p-like modes mainly relate to the structure of the envelope; and p-g mixed modes probe the characteristics of the core. Thus, the likelihood ($\mathcal{L}$) for every model comprises these three parts, namely, $\mathcal{L}_{\text{glob}}, \mathcal{L}_{\text{env}}$ and $\mathcal{L}_{\text{core}}$.

The likelihood of global features was calculated using the masses, radii, and surface gravities from dynamical modelling, as well as effective temperatures ($T_{\text{eff}}$) and metallicities ([Fe/H]) from spectra. It is described as

$$\mathcal{L}_{\text{glob}} = \exp \left( - \frac{1}{2n} \sum_{i=1}^{n} \frac{(x_i - u_i)^2}{\sigma_i^2} \right),$$

where $x_i$ and $u_i$ indicate theoretical and observed parameters, and $\sigma_i$ is the uncertainties of observations. The likelihood for the envelope was estimated by comparing p and the most p-like mixed modes from models and observations:

$$\mathcal{L}_{\text{env}} = \exp \left( - \frac{1}{2n} \sum_{i=1}^{n} \frac{(\nu_{\text{model},i} - \nu_{\text{obs},i})^2}{\sigma_{\text{obs},i}^2} \right).$$

Individual g-dominated mixed modes were identified for KIC 4663623, KIC 8410637, and KIC 9970396, (the other three have the problem with the surface correction) and we used them to estimate the likelihood for the core by

$$\mathcal{L}_{\text{core}} = \exp \left( - \frac{1}{2n} \sum_{i=1}^{n} \frac{(\nu_{\text{model},i} - \nu_{\text{obs},i})^2}{\sigma_{\text{obs},i}^2} \right).$$

These three parts gave the final likelihood, described as

$$\mathcal{L} = \mathcal{L}_{\text{glob}} \mathcal{L}_{\text{env}} \mathcal{L}_{\text{core}}.$$
Figure 5. The peak-bagging process of individual mixed modes for KIC 9970396. The whole power spectrum is separated into eight radial-mode orders as shown in the middle. Close inspections of $l = 2$ and 1 modes are plotted on the left and right sides. The colour code was set as same as that in Figure 1, indicating the $P_{\text{signal}}$ of each frequency bin. Red Symbols plotted on the top are theoretical frequencies of the best fitting model. Squares, circles and triangles in the middle represent the p and most-p-like modes for $l = 0$, 1 and 2. Filled symbols are the modes for picking the fitting models, and open symbols are those for guiding the identification of other mixed modes. Circles and triangles on the left and right indicate all theoretical mixed modes in each frequency bin. And their symbol size is scaled with $1/I^2$ ($I$ is mode inertia) by reference to that of the most p-like mode in each degree and order. Larger size indicates the mode to be more p-like and less in inertia. Small blue symbols represent identified observed frequencies.

The best-fitting model of KIC 9970396 based on the likelihood test is given in Fig. 6. It shows that model frequencies fit quite well after the surface correction.

The theoretical models in this work have four independent input parameters, namely, mass ($M$), heavy-element abundance ($Z$), the mixing-length parameter ($\alpha$) and overshooting parameter ($f_{ov}$). Along with age ($\tau$) and two coefficients ($a_{-1}$ and $a_3$), these seven variables specify a particular model. Thus, we can write the probability of a model as

$$p(\text{Model}|\text{Data}) = p(\text{Model})p(\text{Data}|\text{Model}) = \text{prior} \cdot \mathcal{L},$$  \hspace{1cm} (12)$$

where Model = \{M, Z, \tau, \alpha, f_{ov}, a_{-1}, a_3\} and Data = \{T_{\text{eff}}, \log g, [\text{Fe/H}], R, \nu_{l,n}\}. \mathcal{L}$ is the likelihood obtained above. We assumed a flat prior for all model quantities. Then the probability of $\alpha$, $a_{-1}$ and $a_3$ for a star can be calculated by marginalising over all the other model quantities:

$$p(\alpha) = \int p(M, Z, \tau, \alpha, f_{ov}, a_{-1}, a_3)dMdZd\tau df_{ov}da_{-1}da_3, \hspace{1cm} (13)$$

\[ p(a_3) = \int p(M, Z, \alpha, f_{ov}, a_{-1}, a_3) dMdZd\tau d\alpha da_{ov} da_{-1}. \]  
\[ (15) \]

Fig. 7 gives the probability distributions of \( \alpha \), \( a_{-1} \), and \( a_3 \) for the six stars. The histograms mainly follow Gaussian distributions. Some profiles have a sudden drop rather than a smooth decrease at the boundary. The reason is that the MESA ‘grid search’ function was set to only save models that were in reasonable agreement with the observations \( \chi^2 < 8 \). We used a Gaussian function to fit probability distributions, and adopted the centre and 1-\( \sigma \) deviation of the Gaussian profile as the central value and the uncertainty. The results are summarised in Table 4.

Table 4. Calibrated Mixing-Length Parameter and the Two Coefficients in the Surface-Correction Expression (Eq. 6)

| Star        | \( \alpha \) | \( a_{-1} \) | \( a_3 \) |

5 MODEL PARAMETERS

5.1 The Mixing-Length Parameter

The calibrated mixing-length parameters of the six red giants (Table 4) suggest larger \( \alpha \) for evolved stars than that for the Sun \( \alpha_\odot = 1.92 \). The average mixing-length parameter is about 2.20. However, KIC 7037405 converges at significantly different values (2.00). As mentioned, the determination of \( \alpha \) depends greatly on the measurements of the mass (from the binary orbits). Modelling a star with increased mass tends to lead to a smaller mixing-length parameter when other constraints are kept fixed. Hence systematic errors in mass can bias the results. KIC 7037405, 9540226, and 9970396 were also recently studied by Brogaard et al. (2017). They obtained masses that differ by -2\( \sigma \) for KIC 7037405, 0.96\( \sigma \) for KIC 9540226, and 1.25\( \sigma \) for KIC 9970396. The results suggest that KIC 7037405 could have
Figure 7. Probability distributions for the mixing-length parameter ($\alpha$) and the two coefficients ($a_{-1}$ and $a_3$) for the surface correction. Histograms are normalised proportional to the highest peak. $a_{-1}$ and $a_3$ are scaled by $10^{-9}$ and $10^{-7}$ µHz. Solid curves are the Gaussian profiles for fitting the probability distributions. Red dotted lines indicate solar values, which are 1.92 for $\alpha$ (Paxton et al. 2011), $1.73 \times 10^{-9}$µHz for $a_{-1}$ and $-2.25 \times 10^{-7}$µHz for $a_3$ (Ball & Gizon 2014).
a larger mixing-length parameter than what was obtained (2.00) while KIC 9540226 and KIC 9970396 may converge at a slightly smaller $\alpha$.

The average $\alpha$ obtained for our six giants is $\sim 1.14 \pm 0.07$ times of the calibrated solar value. This result is similar to that achieved by Tayar et al. (2017) with the APOGEE-Kepler targets. Their grid models for the red giants within the range of metallicity ([Fe/H]) from $-0.5$ to $+0.4$ required a $\sim 8\%$ larger $\alpha$ than the Sun to fit the observations. Tayar et al. (2017) also suggested a linear correlation between $\alpha$ and [Fe/H]. However, we did not obtain a clear dependence between the two parameters in our stars.

The realistic simulation of convection is another approach to estimate the mixing-length parameter. Magic et al. (2015) calibrated $\alpha$ with the STAGGER grid, which predicted slightly smaller values ($0.90 - 0.95 \alpha_{\odot}$) for red giants ($T_{\text{eff}} \simeq 5,000$K and $\log g \simeq 2.5$) than that for the Sun. An earlier work by Trampedach & Stein (2011) found the mixing-length parameter to be $0.96 - 1.00 \alpha_{\odot}$ for the red giants having similar stellar parameters with our stars ($M = 0.8 - 2.5 M_{\odot}$, $T_{\text{eff}} = 4200 - 5500$K, $\log g = 2.4 - 3.0$) through 3-D simulations (Trampedach et al. 2014). The $\sim 16\%$ difference of the 1-D stellar model from the simulations may indicate an improper modelling for the near-surface layers in the 1-D model with the current input physics. Firstly, the mixing-length parameter of a star varies for different evolutionary stages (Magic et al. 2015; Trampedach et al. 2014), however, we fixed the mixing-length parameter through the stellar evolution. Secondly, the boundary conditions for red giants can be different from the Sun due to the changes in structures. Moreover, the systematic offsets in observed effective temperatures and metallicities could also affect the results.

5.2 The Surface Term in Evolved Stars

The surface effect, which correlates with the near surface properties, is believed to be a function of $T_{\text{eff}}$ and $\log g$ (Sonoi et al. 2015). The comparison between hydrodynamical simulations and stellar models (Ball et al. 2016) suggested an increasing surface term for dwarfs from the spectral type of K5 to F3. Trampedach et al. (2017) estimated the frequency shifts in various types of stars with a grid of convection simulations and also gave a clear correlation between the surface term and atmospheric parameters.

The frequency offsets caused by the surface term in the best-fitting models of our six red giants are given in Fig. 8. All these stars resulted in the offsets in order of 0.1 $\mu$Hz at $\nu_{\text{max}}$. We compare our results with previous studies in Fig. 9, which gives the distribution of absolute ($\delta\nu$) and relative ($\delta\nu/\nu_{\text{max}}$) frequency offsets as function of the location in the HR diagram. In order to compare with previous results, we also included the six low luminosity red giants studied by Ball & Gizon (2017) as well as the simulation values given by Sonoi et al. (2015) and Trampedach et al. (2017). Modelling results between low and high luminosity red giants show an apparent reduction in both absolute and relative offsets when stars become more evolved. The decreasing $\delta\nu$ on the red giant branch from modelling agrees with the trend predicted by simulation. However, the fractional change ($\delta\nu/\nu_{\text{max}}$) does not follow the simulation results.

Apart from the improper modelling for the surface layers, the uncertainty of the mixing-length parameter also affects the surface term. Fig. 10 shows the correlation between the mixing-length parameter and the surface-correction coefficient of the cubic term ($a_3$). The surface term, as expected, shows a strong dependence on the input $\alpha$ of the model. It varies by a factor ranging from 1.5 to 2 for different stars when the mixing length parameter changing from 1.9 (the solar value) to 2.2 (the red giants value). This is to say, if $\alpha$ cannot be handled well, the surface term will come with significant scatter. Hence the calibrated mixing-length parameter for the six red giants also provide a good constraint on the surface term coefficients. We state here that the degeneracy between $\alpha$ and $a_3$ does not influence our results in Fig. 7, as we have marginalised over all other variables when deriving the posteriors, so these degeneracies are captured in the uncertainties.

A further comparison of the coefficients of stars at different evolutionary stages is given in Fig. 11. Besides the low-luminosity giants from Ball & Gizon (2017) and the high-luminosity giants in this work, we also selected 27 main-sequence dwarfs from the LEGACY sample. These stars cover a range from 0.75 to 1.15$M_{\odot}$, $T_{\text{eff}} = 5500 - 6200$K and $\log g = 4.2 - 4.5$. The comparison shows a significantly increase of $a_{-1}$ and $a_3$ with stellar evolution. We note that the increase is because of the growth of mode inertia, not indicating an increasing surface term with stellar evolution. On the contrary, the fractional frequency offsets ($\delta\nu/\nu_{\text{max}}$) decrease with stellar evolution. Moreover, a good linear relation between $a_{-1}$ and $a_3$ shows in our six red giants: $a_3 \sim -10 a_{-1}$. This agrees with the simulation result from Trampedach et al. (2017), who found a stable ratio between the inverse and cubic terms for red giants with similar $T_{\text{eff}}$ and $\log g$.

6 CONCLUSIONS

The mixing-length parameter in stellar models, responsible for the strength of energy transport in convective regions, is important for the accuracy of the theoretical model. Moreover, the surface term affects the accuracy of asteroseismic modes and brings additional uncertainties in seismic products. In this work, six oscillating red giants in eclipsing binaries were used to calibrate these parameters for evolved stars. Our main conclusions from the results are summarised as follows:

(i) The average mixing-length parameter of the six red giants is $\sim 1.14 \pm 0.07$ times the calibrated solar value, which is similar with the previous results based on the APOGEE sample (Tayar et al. 2017).

(ii) Our calibrated $\alpha$ is about 16\% higher than the value given by the 3-D hydrodynamical simulations, possibly indicating that the 1-D stellar model does not model the near-surface layers appropriately for the red giants with the input physics in this work.

(iii) The surface term was found to affect the mixed modes indirectly. Its effect on acoustic waves changes the frequency range where the p-g coupling happens.

(iv) For our six red giants, established surface-correction methods fail to fix the surface effects in g-dominant modes, which cause a non-physical reordering in mixed modes.
Figure 8. Frequency offsets caused by the surface term of the best-fitting models of our six red giants. Three stars with their $l = 1$ mixed modes identified are shown on the top, where upper panels include $p$ and the most $p$-like modes for $l = 0$ and 2, and lower panels contain $p$-$g$ mixed modes for $l = 1$. The other three stars with only $p$ and the most $p$-like modes are shown at the bottom. Blue and red symbols represent the frequency offsets before and after the surface correction. Open squares, triangles, and circles indicate $l = 0$, 1, and 2 modes. Error bars are observation uncertainties.

(v) The surface term correlates with surface properties ($T_{\text{eff}}$ and $\log g$) as well as the mixing-length parameter. The frequency offset decreases with stellar evolution on the red giant branch.

Figure 9. Absolute (left) and relatively (right) frequency shifts across the HR diagram. The red giants studied in this work and six low-luminosity giants from Ball & Gizon (2017) are shown by squares. Filled triangles and circles are simulating predictions from Sonoi et al. (2015) and Trampedach et al. (2017). Frequency shifts are colour scaled according to the colour bar shown on the top.

Figure 10. The correlation between the mixing-length parameter and the surface term. The coefficient of the cubic term ($a_3$) is from the best-fitting model for each star.

(vi) The two coefficients ($a_{-1}$ and $a_3$) in the surface-correction expression (Eq. 6) significantly increase with stellar evolution due to the growth of mode inertia. They also show a linear correlation in the six red giants. The calibrated results of the mixing-length parameter and the surface term on the six red giants can be additional...
Figure 11. The correlation of two free coefficients (\(a_{-1}\) and \(a_{3}\)) in surface correction expression (Eq. 6). Filled squares indicate the results of our red giants. Open circles represent the 6 low-luminosity giants from Ball & Gizon (2017). Open diamonds are 27 dwarfs from the LEGACY sample. Solar value is represented by \(\odot\).

ACKNOWLEDGEMENTS

We gratefully acknowledge the entire Kepler team and everyone involved in the Kepler mission for making this paper possible. Funding for the Kepler Mission is provided by NASA’s Science Mission Directorate. The authors thank Jørgen Christensen-Dalsgaard for fruitful discussions of the asteroseismic surface term and the oscillation code (ADIPLS), Sanjib Sharma for the fruitful discussion of the Bayesian method, and Karsten Brogaard for the helpful comments during the KASOC review. This work is supported by an Australian Research Council DP grant DP150104667 awarded to JBH and TRB, the Danish National Research Foundation (Grant DNRF106), grants 11503039, 11427901, 11273007, and 10933002 from the National Natural Science Foundation of China, and the Deutscher Akademischer Austauschdienst (DAAD) through the Go8 Australia-Germany Joint Research Co-operation Scheme. WHB acknowledges funding from the UK Science and Technology Facilities Council (STFC).

Figure 1. The peak-bagging process of individual mixed modes for KIC 4663623. The whole power spectrum is separated into eight radial-mode orders as shown in the middle. Close inspections of $l = 2$ and $1$ modes are plotted on the left and right sides. The colour code was set as same as that in Figure 1, indicating the $P_{\text{signal}}$ of each frequency bin. Red Symbols plotted on the top are theoretical frequencies of the best fitting model. Squares, circles and triangles in the middle represent the $p$ and most-$p$-like modes for $l = 0$, 1 and 2. Filled symbols are the modes for picking the fitting models, and open symbols are those for guiding the identification of other mixed modes. Circles and triangles on the left and right indicate all theoretical mixed modes in each frequency bin. And their symbol size is scaled with $1/I^2$ ($I$ is mode inertia) by reference to that of the most $p$-like mode in each degree and order. Larger size indicates the mode to be more $p$-like and less in inertia. Small blue symbols represent identified observed frequencies.
Figure 2. Observed and theoretical échelle diagram of KIC4663623. Black symbols are observed modes. Blue and red symbols indicate model frequencies before and after the surface correction.
