Abstract

Background: Eukaryotic translation initiation factor 4-gamma 1 (EIF4G1) gene mutations have recently been reported in autosomal dominant, late-onset Parkinson’s disease (LOPD). We carried out genetic analysis to determine the prevalence of EIF4G1 variants in an ethnic Chinese population and to better understand the association between EIF4G1 and PD.

Methods: We conducted a comprehensive genetic analysis of EIF4G1 in a cohort of 29 probands of autosomal dominant, LOPD families. Polymerase chain reaction (PCR) analysis and sequencing was carried out of the entire EIF4G1 exonic regions and exon-intron boundaries. Specific mutation and exonic variants were chosen for further sequencing in a case–control study including 503 sporadic PD and 508 healthy controls. Statistical significance was analyzed by the Chi-square test.

Results: Our analysis revealed three exonic variants (rs2230571, rs13319149 and rs2178403) and eight intronic variants across the entire EIF4G1 gene. No reported mutations were detected in EIF4G1 exonic regions. The synonymous coding variant rs2230571 in exon 27 and the eight intronic variants were not used for further sequencing, but the specific mutation c.3614G > A (p.R1205H) and the two nonsynonymous variants (rs13319149 and rs2178403) were chosen for further analysis in a case–control study. None of the 503 sporadic PD or 508 healthy controls carried p.R1205H, and there was no statistical significance in rs2178403 genotype or allele frequencies in EIF4G1 between the PD cases and the healthy controls (p = 0.184 and p = 0.774, respectively; Chi-square test). The rs13319149 genotype in all PD cases and healthy controls was GG.

Conclusions: Our data indicate that in an ethnic Chinese population, the pathogenic mutation p.R1205H in EIF4G1 is not common and that EIF4G1 exonic variants rs2178403 and rs13319149 are not associated with PD. EIF4G1 does not appear to be a frequent cause of PD in this ethnic Chinese population.

Keywords: EIF4G1, Parkinson’s disease, Ethnic Chinese
lation initiation complex is a large family [16,17], including eukaryotic translation initiation factor 4E (eIF4E) and eukaryotic translation initiation factor 3e (eIF3e) that interact with each other and conduct normal translation initiation activity [14,18,19]. In the Chartier-Harlin study [14], it was predicted that mutations p.A502V and p.R1205H disrupt eIF4G1 binding to eIF4E or eIF3e, resulting in PD. Subsequent sequencing and genotyping analysis also identified different EIF4G1 mutations in affected subjects with familial parkinsonism and idiopathic Lewy body disease in different populations.

To obtain a comprehensive view of the prevalence of EIF4G1 variants in an ethnic Chinese population, we conducted a comprehensive genetic screening of EIF4G1 in a Han Chinese group of subjects.

### Methods

#### Patients

The study comprised 29 probands of PD families compatible with autosomal dominant inheritance (two or more PD cases in at least two consecutive generations) and 503 sporadic PD patients of Chinese Han ethnicity from Hunan, Hubei, Jiangxi, Sichuan and Chongqing provinces of China. All patients were consecutively recruited from the Department of Neurology of Xiangya Hospital (Central South University, State Key Laboratory of Medical Genetics of China) and the Neurodegenerative Disorders Research Center. A standard clinical neurological examination was performed for all patients by two neurologists, and a diagnosis of idiopathic PD was made according to the United Kingdom PD Brain Bank Criteria [20].

There were 13 male and 16 female PD patients among the 29 autosomal dominant, LOPD probands, with a mean age at onset of 50.33 ± 9.56 years (range, 41–63 years). Of the 503 sporadic PD patients, 269 were male and 234 were female with a mean age at onset of 55.25 ± 12.21 years (range, 22–81 years). The case–control study also included 508 healthy controls (268 males and 240 females; average age at examination, 56.95 ± 15.20 years, range, 25–88 years) matched for age, gender, ethnicity and area of residence. The control subjects were healthy people from the Xiangya Hospital Medical Center, and healthy volunteers with no history of neurodegenerative diseases. A standard clinical neurological examination was performed on all control subjects, and a diagnosis of possible idiopathic PD was excluded according to the United Kingdom PD Brain Bank Criteria. There was no statistically significant difference in age or gender between patients and controls (p > 0.05, using Chi-square test). The study protocol was approved by the Ethics Committee of Central South University and written informed consent was obtained from all patients and controls.

#### Table 1 EIF4G1 gene variants in 29 probands of LOPD families

| Exonic/intronic variants | Accession number | Nucleotide change | Amino acid change | Frequency of variant in LOPD families (%) |
|--------------------------|------------------|------------------|------------------|------------------------------------------|
| Intron 2                 | rs73187631       | IVS2-182 a > t   |                  | 7.41                                     |

* Values after correcting by binary logistic regression with age and gender using SPSS 17.0: * p = 0.713, *p = 0.702.
Genetic analysis
Genomic DNA was extracted from peripheral blood using standard protocols. Polymerase chain reaction (PCR) analysis was carried out using 20 primer pairs (Additional file 1: Table S1, available online), and each PCR product was purified and directly sequenced in both forward and reverse directions on an ABI 3100 automated sequencer (Applied Biosystems, Foster City, CA). We initially sequenced the entire EIF4G1 exonic regions and exon-intron boundaries of the 29 probands of autosomal dominant, LOPD. Sequence alignment and analysis were carried out with Chromas 2.12 software (Technelysium Pty, Inc., Queensland, Australia).

Statistical analysis
Allele and genotype frequencies of PD and control groups were analyzed using the Chi-square test with SPSS 17.0 software (SPSS Inc., Chicago, IL, USA). A two-tailed test p-value of <0.05 was considered statistically significant.

Results
We identified three exonic variants and eight intronic variants across the entire EIF4G1 gene (Table 1). No reported mutations were detected in the EIF4G1 exonic regions in any of the 29 probands. One of the three exonic variants (exon 25, rs2230571) was synonymous, the other two (rs13319149 and rs2178403) were nonsynonymous.

Neither the synonymous variant nor the eight intronic variants could be sequenced, but the specific mutation p.R1205H in EIF4G1 was confirmed as a candidate PD gene by Chartier-Harlin et al. [14,15], but recently three other variants were reported to cause PD in this ethnic Chinese population. The nonsynonymous exonic variant rs2178403 was in Hardy-Weinberg equilibrium in both the patient and control groups using a goodness-of-fit Chi-square test. Genotype and allele frequencies of rs2178403 for all subjects are shown in Table 2. No statistically significant differences were observed regarding rs2178403 genotype or allele frequency between patients and controls (p = 0.184 and p = 0.774, respectively). Regarding the nonsynonymous exonic variant rs13319149, all patient and control genotypes were GG.

Discussion
EIF4G1 was confirmed as a candidate PD gene by Chartier-Harlin et al. [14,15], but recently three other groups identified EIF4G1 mutations in both PD patients and healthy controls [21-23]. This raises questions about the causality of the gene with regard to PD. In our comprehensive genetic analysis of EIF4G1, we also obtained similar negative results. The specific mutation p.R1205H, first identified by Chartier-Harlin, is important in PD for regulating cell survival in response to stressors [14,15]. However, it was absent from all of our 503 sporadic PD cases and 508 healthy controls suggesting that different populations may have different pathogenic mutations. Alternatively, the effect of the same mutation may differ in different populations, as indicated by the presence of mutation p.R1205H in control individuals of a Central European population shown by Schulte et al. [23].

In the present study, exonic variants rs13319149 and rs2178403 showed no significant difference in either genotype or allele frequencies between PD patients and controls, suggesting that they are probably benign polymorphisms. Although EIF4G1 is considered a pathogenic gene of LOPD, our 29 probands were not typical of LOPD as the average age of onset was 50.33 ± 9.56 years. This may contribute to our negative results, together with the fact that our sample size was relatively small. Further larger-scale genetic studies should therefore be performed to validate our findings.

Conclusions
To our knowledge, this is the first study to assess the frequency of EIF4G1 variants in a cohort of Chinese PD patients and controls. Our results suggest that in this ethnic Chinese population, the pathogenic mutation p.R1205H in EIF4G1 is not common and that nonsynonymous exonic variants rs2178403 and rs13319149 are not associated with PD. Thus, it appears that EIF4G1 is not a frequent cause of PD in this ethnic Chinese population. Further large scale genetic and functional studies would be useful to establish EIF4G1 associations with PD.
