Abstract

The first task of statistical computational linguistics, or any other type of data-driven processing of language, is the extraction of counts and distributions of phenomena. This is much more difficult for the type of complex structured data found in treebanks and in corpora with sophisticated annotation than for tokenized texts. Recent developments in data mining, particularly in the extraction of frequent subtrees from treebanks, offer some solutions. We have applied a modified version of the TreeMiner algorithm to a small treebank and present some promising results.

1 Introduction

Statistical corpus linguistics and many natural language processing applications rely on extracting the frequencies and distributions of phenomena from natural language data sources. This is relatively simple when language data is treated as bags of tokens or as n-grams, but much more complicated for corpora annotated with complex feature schemes and for treebanks where syntactic dependencies are marked. A great deal of useful information is encoded in these more complex structured corpora, but access to it is very limited using the traditional algorithms and analytical tools of computational linguistics. Many of the most powerful techniques available to natural language processing have been built on the basis of n-gram and bag of words models, but we already know that these methods are inadequate to fully model the information in texts or we would have little use for treebanks or annotation schemes.

Suffix trees provide some improvement over n-grams and bag-of-words schemes by identifying all frequently occurring sequences regardless of length (Weiner, 1973; McCreight, 1976; Ravichandran and Hovy, 2002). While this has value in identifying some multi-word phenomena, any algorithm that models languages on the basis of frequent contiguous string discovery will have trouble modeling a number of pervasive phenomena in natural language. In particular:

- Long distance dependencies – i.e., dependencies between words that are too far apart to be accessible to n-gram models.
- Flexible word orders – languages usually have contexts where word order can vary.
- Languages with very rich morphologies that must be taken into account or where too much important information is lost through lemmatization.
- Correlations between different levels of abstraction in annotation, such as between the lemma of a verb and the semantic or syntactic class of its arguments.
- Extra-syntactic correlations that may involve any nearby word, such as semantic priming effects.

In treebanks and other annotated corpora that can be converted into rooted, directed graphs, many of these phenomena are accessible as frequently recurring subtrees. For example, consider the Dutch idiom “naar huis gaan”, (to go home).

The components of this phrase can appear in a variety of orders and with words inserted between the constituents:

1. Ik zou naar huis kunnen gaan. (I could go home.)
2. We gaan naar huis. (We’re going home.)

In a treebank, these two sentences would share a common subtree that encompasses the phrase “naar huis gaan”, as in Figure 1. Note that for this purpose, two subtrees are treated as identical if the
Only difference between them is the order of the children of some or all the nodes.

Most theories of syntax use trees to represent interlexical dependencies, and generally theories of morphology and phonology use either hierarchical tree structures to represent their formalisms, or use unstructured bags that can be trivially represented as trees. Most types of linguistic feature systems are at least in part hierarchical and representable in tree form. Because so many linguistic phenomena are manifest as frequent subtrees within hierarchical representations that are motivated by linguistic theories, efficient methods for extracting frequent subtrees from treebanks are therefore potentially very valuable to corpus and computational linguistics.

2 Previous and Related Work

Tree mining research is a subset of graph mining focused specifically on rooted, directed acyclic graphs. Although there is research into extracting frequent subtrees from free (unrooted and undirected) trees, free tree mining usually proceeds by deciding which node in any particular tree will be treated as a root, and then treating it as if it was a rooted and directed tree (Chi et al., 2003).

Research on frequent subtree discovery generally draws heavily on early work by Zaki (2002) and Asai et al. (2002) who roughly simultaneously began applying the Apriori algorithm to frequent tree discovery (Agrawal et al., 1993). For a summary of Apriori, which is widely used in data mining, and a short review of its extensive literature, see Kotsiantis and Kanellopoulos (2006). A broad summary of algorithms for frequent subtree mining can be found in Chi et al. (2004).

Research into frequent substructures in computational linguistics is quite limited. The Data Oriented Processing model (Bod et al., 2003) along with its extension into machine translation - the Data Oriented Translation model (Poutsma, 2000; Poutsma, 2003; Hearne and Way, 2003) - is the most developed approach to using frequent subtree statistics to do natural language processing. There is also growing work, largely stemming out of DOP research, into subtree alignment in bilingual parsed treebanks as an aid in the development of statistical and example-based machine translations systems (Hassan et al., 2006; Tinsley et al., 2007; Zhechev and Way, 2008).

3 Key concepts

Among the key concepts in tree mining is the difference between bottom-up subtrees, induced subtrees and embedded subtrees. A bottom-up subtree $T''$ of a tree $T$ is a subtree where, for every node in $T''$, if its corresponding node in $T$ has children, then all those children are also in $T''$. An induced

Figure 1: The two Dutch sentences "Ik zou naar huis kunnen gaan" and "We gaan naar huis", parsed, and with the frequent section highlighted. Note that these two subtrees are identical except for the order of the nodes. (N.B.: This tree does not take the difference between the infinitive and conjugated forms into account.)
subsection \( T' \) of \( T \) is a subtree where every node in \( T' \) is either the root of \( T' \) or its parent in \( T \) is also its parent in \( T' \). An embedded subtree \( T'' \) of \( T \) is a subtree where every node in \( T'' \) is either the root of \( T'' \) or its parent in \( T'' \) is one of its ancestors in \( T \). See Figure 2 for an example of different types of subtrees.

Linear time solutions exist for finding all frequent bottom-up subtrees in a treebank because this problem can be transformed into finding all frequent substrings in a string, a problem for which fast solutions are well known (Luccio et al., 2001; Luccio et al., 2004).

Solutions for induced and embedded subtrees draw heavily on Zaki (2002) (the TreeMiner algorithm) and Asai et al. (2002) (the FREQT algorithm), both of whom propose Apriori-style approaches. This type of solution has the general property that runtime is proportionate to the size of the output: the sum of the number of times each frequent subtree appears in the treebank. This is not readily predictable, because the number and frequencies of subtrees is not formally determinable from the size of the treebank and can grow very rapidly.

### 3.1 Ordered and unordered trees

TreeMiner/FREQT approaches require all trees to be ordered so that the nodes of any frequent subtree will always appear in the same order every time it appears. The children of each non-leaf node are sorted into a lexicographic order, but this only guarantees that frequent subtrees will always appear with the same ordering if no node has more than one non-leaf child node with the same label. This is not uniformly true of natural language parse trees, as shown in Figure 3. Solutions exist that remove this limitation - notably Chi et al. (2003) - but they come at a significantly increased processing cost.

### 3.2 Closed trees

Given that this type of approach to subtree discovery has runtime bounds proportionate to the unpredictable size of the output, one way to keep subtree discovery within manageable bounds is to restrict the output. Many of the frequent trees present in treebanks are redundant, since they are identically distributed with other, larger trees, as in Figure 4.

If a corpus has a sequence of tokens \( ABCDE \) that appears \( f \) times, then that corpus also contains at least \( f \) instances of the sequences \( A, B, C, D, E, AB, BC, CD, DE, ABC, BCD, CDE, ABD, \) and \( BCDE \). If any of these sequences appears only in the context of \( ABCDE \), then they are redundant, because they have the same count and distribution as the longer sequence \( ABCDE \).

If a set of sequences is identically distributed - appearing in all the same places - then the longest of those sequences is called a closed sequence. In more formal terms, a sequence \( S \) that appears \( f \) times in a corpus is called closed if and only if there is no prefix or suffix \( a \) such that \( aS \) or \( Sa \) also appears \( f \) times in the corpus. This definition extends easily to trees: A subtree \( T \) in a treebank is closed if and only if there is no node that can be added to it to produce a new subtree \( T' \) such that the frequency of \( T' \) is equal to the frequency of \( T \).

All subtrees in a corpus are either closed subtrees or are subtrees of closed subtrees that appear in exactly the same places in the treebank. The set of closed subtrees in a treebank is the smallest set of subtrees that encompasses all the distributions of subtrees in the treebank. Any subtree that is not in the list of closed subtrees is either a subtree of one of the closed subtrees that appears exactly as often and in all the same places, or does not appear in the treebank at all.

There are algorithms that extract only closed subtrees from treebanks - notably Chi et al. (2005a) - and thereby increase their speed dramatically without producing less
4 Algorithm and data structures

The algorithm used in this research is an extension of the TreeMiner algorithm (Zaki, 2002), modified to extract only closed subtrees. It takes a minimum frequency threshold as a parameter and extracts only those subtrees which are closed and whose frequency is at least equal to the threshold. This algorithm suffers from the same shortcoming of Zaki’s original algorithm in that it is only guaranteed to find all frequent subtrees among ordered trees where no node has two non-leaf children with the same label.

It has one novel property which it appears not to share with any other subtree extraction scheme to date: This algorithm outputs subtrees in order from the most frequent to the least. Given the difficulty of predicting in advance how large the output will be, and the large size of many natural language data sources, this can be a real boon. If output size or memory usage grow too large, or too much time has passed, the program can be stopped while still guaranteeing that it has not missed any more frequent subtree than the last one outputted.

This section can only very briefly describe the algorithm.

4.1 Definitions

A treebank is any collection of trees where each node bears a label and each node is uniquely addressable in such a way that the address \( a_n \) of a node \( n \) is always greater than the address \( a_p \) of its parent \( p \). This is accomplished by representing all trees as ordered depth-first canonical strings. (See Chi et al. (2005b).)

Each appearance of a subtree within a treebank is characterized by the address of its root in the treebank and the address of its rightmost node. This data structure will be called a Hit. The list of all Hits corresponding to all the appearances of some subtree in the treebank will be called a HitList. So, for each subtree there is a corresponding HitList and vice-versa. HitLists are always constructed in sequential order, from first instance in the treebank to last, and can never contain duplicates.

We will define the function queueKey on HitLists to output an array of four numbers in a specific order, given a HitList as input:

1. The number of Hits in the HitList.
2. The distance from the address of the root of the first Hit to the end of the treebank.
3. The distance from the address of the rightmost node of the first Hit to the end of the treebank.
4. The number of nodes in the subtree associated with that HitList.

These keys are sortable and designed to ensure that HitLists from a single treebank can always be sorted into a fixed order such that, for two HitLists \( A \) and \( B \), if \( A > B \) then:

1. \( A \) has more Hits than \( B \).
2. If \( A \) has the same number of Hits as \( B \), then the root of the first Hit in \( A \) precedes the root of the first Hit in \( B \).
3. If \( A \)’s first root is identical to \( B \)’s, then the address of the rightmost node of the first Hit in \( A \) precedes the address of the rightmost node of the first Hit in \( B \).
4. If the first Hit in \( A \) is exactly the same the first Hit in \( B \), then the subtree associated with \( A \) has more nodes than the subtree associated with \( B \).
A self-sorting queue is any data structure that stores key-data pairs and stores the keys in order from greatest to least. The data structure used to implement a self-sorting queue in this research is an AVL tree (Adelson-Velskii and Landis, 1962), however, other structures could equally well have been used. The self-sorting queue will be used to maintain a sorted list of HitLists, sorted in the order of their queueKeys as described above.

4.2 Initialization
Fix a minimum frequency threshold \( t \) for the subtrees you wish to extract from the treebank. Start processing by initializing one HitList for each unique label in the treebank with the set of Hits that corresponds to each occurrence of that label. We will treat each as a HitList with an associated subtree containing only one node. This set is constructed in linear time by iterating over all the nodes in the treebank.

Of the initial HitLists, throw away all those with fewer than threshold frequency \( t \) Hits in them. The remaining HitLists are inserted into the self-sorting queue.

4.3 Extracting induced subtrees without checking for closure
Extracting all the subtrees above a fixed frequency - not just the closed subtrees - in order from the most frequent to the least, proceeds as follows:

1. Initialize as described in Section 4.2.
2. Pop the top HitList \( hl \) and its associated subtree \( s \) from the queue.
3. Extend \( hl \):
   (a) Visit each Hit in \( hl \) and find all the nodes that can be added to the right side of \( s \) to produce new induced subtrees.
   (b) Generate new HitLists for all subtrees that extend \( s \) by one node to the right.
   (c) Test each new HitList to make sure it appears more than threshold frequency \( t \) times, and if it does, insert it into the queue.
   (d) Output \( s \) and \( hl \).
4. Repeat until the queue is empty.

This is essentially identical to the TreeMiner and FREQT algorithms already published by Zaki (2002) and by Asai et al. (2002), except that it outputs frequent subtrees in order from the most frequent to the least.

4.4 Extracting only closed induced subtrees
By controlling the order in which HitLists reach the top of the queue, it is possible to efficiently prevent any subtree which is not a closed subtree or a prefix of a closed subtree from being extended, and to prevent any subtree that is not closed from being outputted.

Every subtree with a frequency of \( f \) is either a closed subtree, a prefix of a closed subtree that also has a frequency of \( f \) and can be constructed by adding more nodes to the right, or is a redundant non-closed subtree that need not be extended or stored. Consider a redundant, non-closed subtree \( x \) and a closed subtree or prefix of a closed subtree \( y \) which has the same frequency, and has the same set of addresses for the rightmost node of each of its appearances in the treebank. The sort order of the self-sorting queue (see Section 4.1) ensures that if a prefix of a closed subtree \( y \) is in the queue and some subtree of it \( x \) is also in the queue, then \( y \) is closer to the top of the queue than \( x \) is. Furthermore, it can be proven that the prefix of a closed subtree with the same distribution as any non-closed, redundant subtree will be generated, inserted into the queue, and removed from the top of the queue before \( x \) can reach the top.

So, to prevent \( x \) from being extended or stored, all that is necessary is to check to see there is some closed subtree or prefix of a closed subtree \( y \) such that:

- \( y \) has already been at the top of the queue.
- \( y \) has the same frequency as \( x \).
- The set of rightmost nodes of every Hit in \( y \)’s HitList is identical to the set of rightmost nodes of every Hit in \( x \)’s HitList.
- \( x \) is a subtree of \( y \)

This can be checked by constructing a hash value for each HitList based on its frequency and some subset of the set of rightmost nodes of every Hit. In our experiments, we used only the first node of each HitList. If \( x \)’s hash value matches some previously processed \( y \)’s hash value, then check if \( x \) is a subtree of \( y \) and reject it if it is. The result is to only instantiate closed subtrees and their prefixes, and subtrees which are one node extensions of closed subtrees and their prefixes.

Like TreeMiner, worst case space and time bounds are proportionate to the number of subtrees instantiated and the number of times each appears in the corpus. This is smaller than the
worst case bounds for TreeMiner because it does not instantiate all frequent subtrees. There is additional approximately constant time processing for each instantiated subtree to check for closure and to store it in the self-sorting queue. At the lowest frequency thresholds, this can take up the majority of runtime, but is generally negligible at high frequencies.

5 Results

We applied this algorithm to a parsed and hand-corrected 7137 sentence subset of the Alpino Treebank of Dutch.1 The average sentence length in this small treebank is roughly 20 words, and the corresponding trees have an average of approximately 32 nodes for a total of 230,673 nodes. With the minimum frequency set to 2, this algorithm extracted 342,401 closed subtrees in about 2000 seconds on a conventional workstation running Linux2. The same implementation but without testing for closure - which makes this algorithm equivalent to TreeMiner - extracted some 4.2 million trees in roughly 11,000 seconds. Closed tree extraction contrasts quite favorably to extraction without closure, even over a small dataset.

| Min. Freq. Threshold | Subtrees extracted | Runtime  |
|----------------------|--------------------|----------|
| 2                    | 342401             | 1952.33s |
| 3                    | 243484             | 1004.30s |
| 4                    | 176885             | 588.58s  |
| 5                    | 134495             | 402.26s  |
| 8                    | 72732              | 209.51s  |
| 10                   | 53842              | 163.22s  |
| 15                   | 30681              | 112.39s  |
| 20                   | 20610              | 85.24s   |
| 30                   | 11516              | 66.05s   |
| 40                   | 7620               | 54.14s   |
| 50                   | 5549               | 47.98s   |
| 60                   | 4219               | 43.24s   |
| 70                   | 3365               | 39.97s   |

Table 1: Runtime and closed trees extracted at different minimum frequency thresholds, using the 7137 sentence sample of the Alpino Treebank.

Runtime and the number of trees produced fall very dramatically as thresholds rise - so much so that setting the minimum frequency to 3 instead of 2 halved the runtime. This pattern is characteristic of a power law distribution like Zipf’s law. (See Table 1 and Figure 5.) Given the pervasiveness of power law distributions in word frequencies, it should perhaps not be surprising to discover that frequent closed subtrees in treebanks are similarly distributed. This research may be the first effort to empirically support such a conclusion, although admittedly only very tentatively.

To test the impact of varying the size of the treebank, but keeping the minimum frequency threshold constant, we used a section of the Dutch portion of the Europarl corpus (Koehn, 2005) automatically parsed using the Alpino Dutch parser (van Noord, 2006) without any manual correction. Random samples of 2500, 5000, 10000, 15000 and 20000 sentences were selected, and all subtrees of frequency 5 or higher were extracted from each, as summarized in Table 2. As treebank size grows, the number of subtrees extracted at the same minimum frequency threshold, and the time and memory used extracting them, grows exponentially. This is in sharp contrast to algorithms that extract frequently recurring strings, which increase linearly in time and memory usage as the data grows.

However, if the minimum frequency threshold is kept constant as a proportion of the size of the treebank, then the number of trees extracted remains roughly constant and the time and memory used to extract them grows roughly linearly with the size of the treebank. Table 3 shows the result for different sized random samples of the parsed Europarl corpus.

Lastly, since this algorithm has known difficulties when presented with trees where more than one non-leaf child of a node can have the same
Figure 5: Runtime (a) and subtrees extracted (b) from the Alpino sample using different minimum frequency thresholds. Figure (c) is a log-log plot of (b). Figure (c) looks close to a straight line, which is characteristic of a power law distribution.

| Sents | Total nodes | Min. Freq. Thres. | Subtrees extracted | Runtime |
|-------|-------------|-------------------|--------------------|---------|
| 2500  | 99323       | 5                 | 42905              | 72.95s  |
| 5000  | 194736      | 10                | 42783              | 122.18s |
| 10000 | 382022      | 20                | 41988              | 216.23s |
| 15000 | 574632      | 30                | 43078              | 325.86s |
| 20000 | 770240      | 40                | 44416              | 435.19s |

Table 3: Runtime and closed trees extracted from automatically parsed samples of the Europarl Dutch corpus, with minimum frequency thresholds kept roughly constant as a proportion of the sample size.

Table 4: Non-closed trees from the 7137 sentence sample of the Alpino Treebank, produced erroneously as closed trees because of repeated labels. There were no non-closed trees extracted at frequencies over 30.

6 Conclusions

The algorithm presented above opens up treebanks and annotated corpora to much more detailed quantitative analysis, and extends the tools available for data-driven natural language processing. This makes a number of new applications possible. We are developing treebank indexing for fast retrieval by tree similarity, in order to make full treebanks available for example-based parsing and machine translation in real time. This algorithm also has applications in constructing concordances of syntactic, morphological and semantic structures - types of information that are not traditionally amenable to indexing. Furthermore, statistical models of natural language data can take
advantage of comprehensive subtree censuses to become fully syntax-aware, instead of relying on bag of words and n-gram models.

However, there are a number of drawbacks and caveats that must be highlighted.

Runtime, memory usage and output size are difficult to estimate in advance. This is mitigated in part by the order in which subtrees are outputted, making it possible to extract only the most frequent subset of subtrees given fixed time and space bounds. Empirically, it appears that resource requirements and output size can also be estimated by sampling, if minimum frequency thresholds can be kept constant as a proportion of total treebank size.

The formalisms used in most theories of syntax allow nodes to have multiple non-leaf children with the same labels. Although errors caused by non-unique labels are overwhelmingly present only among the lowest frequency subtrees, errors appear often enough to pose a non-negligible problem for this algorithm.

We are investigating the degree to which this can be mitigated by making different choices of linguistic formalism. Syntax trees that contain only binary trees - for example, those constructed using Chomsky Normal Form rules (Jurafsky and Martin, 2009) - cannot have identically labelled non-leaf children, but must suffer some loss of generality in their frequent subtrees because of it. Other theories can reduce the size of this source of error, notably dependency syntax which often uses fewer abstract labels (Tesnière, 1959; Mel’čuk, 1988; Sugayama and Hudson, 2006), but will most likely be poor sources of highly general rules as a consequence.

Furthermore, tree mining algorithms exist that eliminate this problem, but at some cost. We are investigating a hybrid solution to the non-unique label problem that identifies only those subtrees where more resource-intensive closure checking is necessary. This will guarantee the correct extraction of closed subtrees in all cases while minimizing the additional processing burden.

Among the open problems suggested by this research is the degree to which the empirical results obtained above are dependent on the language of the underlying data and the linguistic formalisms used to produce treebanks. Different linguistic theories use different abstractions and use their abstract categories differently. This has an immediate effect on the number of nodes in a treebank and on the topology of the trees. Some theories produce more compact trees than others. Some produce deep trees, others produce shallow trees. It is likely that the formalisms used in treebanks have a pervasive influence on the number and kind of frequent subtrees extracted. By doing quantitative research on the structures found in treebanks, it may become possible to make reliable operational choices about the linguistic formalisms used in treebanks on the basis of the kinds of structures one hopes to get out of them.
