ABSTRACT
An exceptional $\gamma$-ray outburst from 3C 279 was detected by the Fermi-Large Area Telescope (LAT) in 2015 June. In the energy range of 0.1–300 GeV, the highest flux measured is $(39.1 \pm 2.5) \times 10^{-6}$ ph cm$^{-2}$ s$^{-1}$, which is the highest $\gamma$-ray flux ever detected from 3C 279, exceeding the previous historically brightest flare observed by EGRET in 1996. The high activity period consists of three major flares with the last one being the brightest. All but one flare show a faster rise and slower decay pattern, and at the peak of the activity, the $\gamma$-ray spectrum is found to show a clear signature of break/curvature. The obtained spectral parameters hint that the peak of the inverse Compton emission lies in the LAT energy range (around $\sim$1 GeV), which is in contrast to that seen during the 2013 December and 2014 April $\gamma$-ray flares of 3C 279. From the $\gamma\gamma$ pair opacity arguments, the minimum Doppler factor is estimated to be 14, and the location of the $\gamma$-ray emitting region is found to be either at the outer edge of the broad line region or farther out from it.

Key words: galaxies: active – gamma rays: galaxies – quasars: individual (3C 279)

1. INTRODUCTION

The radio source 3C 279 ($z = 0.536$; Lynds et al. 1965) is one of the best-studied flat-spectrum radio quasars (FSRQs) in all of the wavebands. It emits strong and variable emission at all frequencies and is one of the first blazars detected by the EGRET instrument on the Compton Gamma-ray Observatory (Hartman et al. 1992). Since 2008, 3C 279 has been continuously monitored by the Fermi-large Area Telescope (LAT) and was a subject of various multi-wavelength campaigns (e.g., Hayashida et al. 2012, 2015). This source is an active $\gamma$-ray emitter, and multiple episodes of $\gamma$-ray outbursts have been detected (Hayashida et al. 2012; Paliya et al. 2015). In particular, two prominent flares of similar intensity ($F_{\gamma,100}$ $\sim 12$, where $F_{\gamma,100}$ is the $\gamma$-ray flux in the 0.1–300 GeV range and in units of $10^{-6}$ ph cm$^{-2}$ s$^{-1}$) have been detected by LAT in 2013 December and 2014 April. Interestingly, the 2013 December flare exhibited a hard rising spectrum, whereas a significant curvature was noticed in the 2014 April flare (Hayashida et al. 2015; Paliya et al. 2015). A $\gamma$-ray flux variability as short as $\sim$1 hr was also reported (Paliya et al. 2015).

In 2015 June, 3C 279 displayed an exceptionally high activity state. The daily binned $\gamma$-ray flux was reported as the highest measured since the beginning of the Fermi operation (Cutini 2015). Two targets of opportunity observations were approved for a total duration of 750 ks (between MJD 57,188 and 57,197), and during this period, Fermi observed 3C 279 in a special pointed mode other than its normal sky scanning mode operation. In this Letter, motivated by the availability of good-quality LAT data, the intraday $\gamma$-ray variability and associated spectral changes are studied in detail. The obtained results are further compared with the previous major flares detected from 3C 279. In Section 2, observations and data analysis of the Fermi-LAT data from 2015 June 7 to 20 (MJD 57,180–57,193) are reported. Results are presented in Section 3 and discussed in Section 4. Throughout, a $\Lambda$CDM cosmology with the Hubble constant $H_0 = 71$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.27$, and $\Omega_{\Lambda} = 0.73$ is adopted.

2. FERMI-LAT OBSERVATIONS

To analyze the LAT data (P7REP) covering the period of the $\gamma$-ray outburst, the standard data reduction procedure is adopted, and here it is described in brief. The unbinned likelihood method included in the ptool library of the Science Tools (v9r33p0) is used to extract the information from the events belonging to the SOURCE class and energy range 0.1–300 GeV and lying within $10^\circ$ of the region of interest (ROI) centered at the position of 3C 279. A maximum likelihood (ML) test statistic $TS = 2\Delta\log(\mathcal{L})$, where $\mathcal{L}$ represents the likelihood function between models with and without a point source at the position of the source of interest, is calculated to determine the significance of the $\gamma$-ray signal. All the sources lying within the ROI and defined in the third Fermi-LAT catalog (3FGL; Acero et al. 2015) are included, and their spectral parameters are left free to vary during the model fitting. Sources lying within $10^\circ$ to $15^\circ$ from the center of the ROI also appeared in the model file, and their parameters are kept fixed at the 3FGL catalog values. A first run of the ML analysis is performed over the period of interest, and all the sources with $TS < 25$ are removed from further analysis.

To characterize the variability properties of the source, light curves are generated using various time binnings (3 hr, 6 hr, and 1 day) and over different energy intervals (0.1–300 GeV, 0.1–1 GeV, and 1–300 GeV). Though the $\gamma$-ray spectral shape of 3C 279 exhibits a definite curvature, all the light curves are produced by adopting a simple power law (PL) in each time bin since the statistical uncertainties on the PL indices are smaller compared to those obtained from complex model fits such as a broken power law (BPL). Various models are applied to fit the $\gamma$-ray spectra of 3C 279 and that includes a BPL ($N(E) = N_0(E/E_{\text{break}})^{-\alpha}$, with $i = 1$ if $E < E_{\text{break}}$ and $i = 2$ if $E > E_{\text{break}}$), a log-parabola ($N(E) = N_0(E/E_p)^{-\alpha-\beta \log(E/E_p)}$, where $\alpha$ is the photon index at $E_p$, $\beta$ is the curvature index, and $E_p$ is fixed at 300 MeV), and a PL model over equally spaced logarithmic energy bins with $\Gamma$ kept fixed to the value fitted over the whole energy range.
Due to good photon statistics, the light curves are also generated using time bins of 12, 6, and 3 hr and are shown in the bottom three panels of Figure 1. As can be seen, the flare of period P1 starts getting resolved in finer bin light curves. In fact, this period comprises two flares distinctly visible in the 6 hr binned light curve. There is a third sharp flare as P1 ends and P2 begins. These three flares are named F1, F2, and F3 for the rest of the analysis (see Figure 1). The rising phase of the brightest flare, F3, is clearly unresolved down to a 3 hr scale, whereas its decaying segment seems to be nicely resolved in 6 hr binning. Though the flares F1 and F2 appear to be resolved in 6 hr binning, the 3 hr binning light curve suggests that the presence of sub-structures consisting of several large amplitudes are yet unresolved and exhibit chaotic events. The highest γ-ray flux, using 3 hr binning, is obtained as $F_{\text{GeV}} = 33.5 \pm 1.4$. Moreover, the data are also analyzed using the time bins defined as good time intervals (GTI; Foschini et al. 2011). The highest γ-ray flux measured using this method is $F_{\text{GeV}} = 39.1 \pm 2.5$, thereby making this peculiar γ-ray flare the brightest event recorded from 3C 279 not only since the beginning of Fermi operation but also ever. For a comparison, the historically brightest flare was detected by EGRET when the measured flux was as high as $\approx 2 \times 10^{-8} \text{ph cm}^{-2} \text{s}^{-1}$ (Wehrle et al. 1998). Further, the associated GTI bin size was $\approx 14$ minutes with TS = 2407 and 275 counts were registered.

To determine the duration of the shortest flux variability, the light curves are scanned using the following equation:

$$F(t_2) = F(t_1) \exp \left( \frac{t_2 - t_1}{T_t} \right)$$

where $F(t_1)$ and $F(t_2)$ are the fluxes at time $t_1$ and $t_2$, respectively, and $T_t$ is the flux doubling/halving timescale. The shortest flux doubling time using this method is measured as $2.2 \pm 0.3$ hr on MJD 57,189 with $\approx 9\sigma$ significance. Moreover, in order to assess the asymmetry of the rise and decay of flares, all the three flares (F1, F2, and F3) are also subjected to temporal profile fitting. This is done for 6 hr binned flares, and the fitting is performed by including a constant background and three fast, temporally evolving components. Each flare is approximated to be fit by a function of the following form:

$$F(t) = 2F_0 \exp \left( \frac{t_0 - t}{T_t} \right) + \exp \left( \frac{t - t_0}{T_d} \right)$$

(2)

(Abdo et al. 2010), where $F_0$ is the flux at time $t_0$ representing approximately the flare amplitude, and $T_t$ and $T_d$ are the rise and decay time of the flare. The obtained rising times for F1, F2, and F3 are $5.40 \pm 0.84$ hr, $4.05 \pm 2.73$ hr, and $3.06 \pm 0.57$ hr, respectively, whereas the associated decay time of the flares are $9.91 \pm 5.04$ hr, $4.13 \pm 2.02$ hr, and $8.68 \pm 0.42$ hr, respectively. The result of the time profile fitting is shown in Figure 2.

LAT γ-ray light curves of 3C 279, focusing on the flare period in two different energy bands: $0.1$–$1$ GeV and $1$–$300$ GeV, are shown in the top panel of Figure 3. The $1$–$300$ GeV light curve is scaled appropriately to compare its variability pattern with that seen in the $0.1$–$1$ GeV range. As can be seen, though the pattern of flux variations are similar in both the bands during the F3 flare, there are very moderate changes in source brightness in the $1$–$300$ GeV band compared to $0.1$–$1$ GeV for the F1 and F2 events. This observation indicates that the F1 and F2 flares are primarily caused by low...
are 6 hr binned

\[ \text{time ordering is} \]

Bottom: DCF calculated for the 0.1–300 GeV energy ranges, respectively. Though there are no significant spectral hardening/softening during the F1 and F2 flares, the spectrum is clearly hard at the peak of F3, and it softens as the flare decays (see the middle panel of Figure 3). Further, recently it has been proposed that the origin of γ-ray flares that lie inside/outside the BLR is reflected by the absence/presence of time lag between MeV and GeV emission (Dotson et al. 2012). To test this hypothesis, a time-lag analysis is performed using the \emph{z-transformed discrete correlation function} method of Alexander (2013; see also Alexander 1997). The errors are computed using a Monte Carlo simulation by adding a random error at each step to all data from the errors in the light curves (Alexander 2013). The result of this analysis is shown in the bottom panel of Figure 3. As can be seen, there is no significant lead/lag noticed between the two energy bands (time lag of \(0.0 \pm 0.1\) days). It should be noted that there could be lag between these light curves; however, limited time resolution of the light curves and closeness of the LAT energy bands make it difficult to quantify.

Hints of the presence of spectral evolution can be further investigated by plotting the photon index versus flux. This is done for 6 hr binned data in two energy ranges: 0.1–300 GeV and 0.1–1 GeV, for the periods P1 and P2 (covering the flares F1, F2, and F3). The results are presented in the left panel of Figure 4. For comparison, the averages obtained over the period “Pre,” are also shown with blue squares. A clockwise pattern is evident during the P2 period for both energy bands. Though there are hints of the same behavior during the P1 period in the 0.1–300 GeV energy range, the 0.1–1 GeV plot shows clear evidence of a clockwise helical pattern. The reduced \(\chi^2\) for a constant fit of the photon index for the period P1 are 6.94/7 and 6.68/7 for 0.1–300 GeV and 0.1–1 GeV, respectively. Comparing to the “Pre” period, a flux enhancement by a factor of 10 is accompanied by a slight hardening of the spectrum. While drawing any firm conclusion on particle acceleration and cooling from these patterns is not possible, the lack of strong spectral variability still provides clues to the underlying physical processes. Due to poor statistics, a clear pattern of the photon index for the energy range 1–300 GeV versus flux could not be observed with 6 hr time binning.

In the right panel of Figure 4, the LAT spectra obtained by averaging the four periods shown in Figure 1 are displayed. These flux distributions have been fitted with PL (dotted), log-parabola (dashed), and BPL (solid) models. Due to low photon statistics during the “Pre” and “Post” periods, the BPL model could not be fitted. To substantiate the presence/absence of the spectral curvature, the TS of the curvature TS_{curve} = 2(\log \mathcal{L} (\text{log-parabola/BPL}) − \log \mathcal{L} (\text{PL})) is also computed (Nolan et al. 2012). The associated parameters are provided in Table 1. Out of all the four periods considered, a statistical significant break/curvature is noticed only during P1 and P2 periods. Both the log-parabola and BPL models reproduce the data satisfactorily, though the log-parabola model gives a slightly better fit. The break energy obtained from the BPL model fitting remains constant, irrespective of the fluctuations seen in the flux levels during both the periods. This finding is in line with that observed during the γ-ray outburst of 3C 454.3 in 2010 November (Abdo et al. 2011).

energy electrons. Further, the hardness ratio is also calculated to assess the spectral evolution as a function of time. This is done using following equation:

\[ \text{HR} = \frac{F_{H} - F_{S}}{F_{H} + F_{S}}. \]
The γ-ray outburst of 3C 279 in 2015 June has broken the record of the highest γ-ray flux ever measured from this blazar. The entire flaring episode is found to comprise three flares with the last one having the largest amplitude. The rising part of the brightest flare is unresolved down to 3 hr binning, and this hints that with the limited time resolution, the apparent profiles of the source flux variations may not reflect the exact temporal characteristics of the γ-ray outburst. However, the decaying part of the flare is nicely resolved in 6 and 3 hr binned light curves.

4. DISCUSSION

The γ-ray outburst of 3C 279 in 2015 June has broken the record of the highest γ-ray flux ever measured from this blazar. The entire flaring episode is found to comprise three flares with the last one having the largest amplitude. The rising part of the brightest flare is unresolved down to 3 hr binning, and this hints that with the limited time resolution, the apparent profiles of the source flux variations may not reflect the exact temporal characteristics of the γ-ray outburst. However, the decaying part of the flare is nicely resolved in 6 and 3 hr binned light curves.

The shortest flux doubling timescale obtained in this work is ~2 hr, which is similar to that obtained during the 2013 December outburst of 3C 279 (Hayashida et al. 2015). Interestingly, comparing to the 2014 April outburst, though the flux level is significantly higher during the 2015 June flare, the faster variability was measured during the former (Paliya et al. 2015). However, similar to the 2013 December and 2014 April flares, the flares of the 2015 June outburst are found to exhibit asymmetric variability patterns with fast rise and slow decay (except for F2), which can be explained by invoking the rapid injection of accelerated electrons, probably
at shock front, and the decay can be attributed to the weakening of the shock.

The minimum Doppler factor $\delta_{\text{min}}$ can be estimated numerically from $\gamma\gamma$ opacity arguments and by measuring the energy of the highest-energy photon detected during the flare. Assuming that the optical depth $\tau_{\gamma\gamma}(\epsilon_0)$ of a photon with energy $\epsilon_1 = E_0/m_e c^2$ to the $\gamma\gamma$ interaction is $\tau_{\gamma\gamma} = 1$, the minimum Doppler factor can be calculated as follows (see, e.g., Dondi & Ghisellini 1995; Ackermann et al. 2010):

$$\delta_{\text{min}} \equiv \left[ \frac{\sigma_T d_L^2 (1 + z)^2 f_0 \epsilon_1}{4\epsilon_0 m_e c^4} \right]^{1/6},$$

where $f_0$ is the flux at energy $\epsilon = h\nu/m_e c^2$ and $\epsilon = \epsilon_0 = 2\epsilon_1/(1 + z)^2 \epsilon_1$ (Ackermann et al. 2010). In this calculation, the energy of the highest-energy photon ($E_1$) is used during the period when time variability $\tau_{\text{var}}$ and $f_0$ are measured. The highest-energy photon of energy $\approx 52$ GeV is detected on MJD 57,189.62 at an angular separation of 0.09" from the 3FGL position of 3C 279, with 99.99% probability of being the source photon (see the bold downward arrow in the bottom panel of Figure 1). Almost at the same time, the Swift X-ray Telescope observation has revealed the energy flux in the 0.3–10 keV band to be $3.5 \times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$ and the associated photon index to be 1.4 (Pittori et al. 2015). Since the highest-energy photon was detected during the fading part of F3, the time variability can be taken as $\tau_{\text{var}} = \ln(2) \times T_d \approx 6$ hr. This gives $\delta_{\text{min}} \approx 14$.

A rough estimation about the location of the emission region ($R_{\text{diss}}$) can be done by assuming it to have spherical geometry and bulk Lorentz factor $\Gamma = \delta_{\text{min}} = 14$. Then $R_{\text{diss}} < 2c\Gamma^2 f_0/(1 + z) \approx 0.05$ pc. Now, considering the accretion disk luminosity ($L_{\text{disk}}$) of 3C 279 to be $1 \times 10^{45}$ erg s$^{-1}$ (Paliya et al. 2015), the size of the BLR comes out to be $\approx 1 \times 10^{18}$ cm $\approx 0.03$ pc (e.g., Kaspi et al. 2007). Therefore, at the time of the 52 GeV photon emission, the $\gamma\gamma$ radiating region must have been located either close to the outer edge of the BLR or beyond it. This is also supported by fact that to avoid severe absorption of high-energy photons (having energy $> 50$ GeV) by optical–UV radiation of the BLR radiation field, the emission region has to be farther out from the BLR.

The highest $\gamma\gamma$ flux measured is $F_{\gamma\gamma} = 39.1 \pm 2.5$, and the associated photon index is $2.0 \pm 0.1$. This corresponds to an isotropic luminosity ($L_{\gamma\gamma}$) of $(5.5 \pm 1.1) \times 10^{49}$ erg s$^{-1}$. Assuming $\Gamma = 14$, the $\gamma\gamma$ luminosity in the jet frame would be $L_{\gamma\gamma,\text{em}} \approx L_{\gamma\gamma}/\Gamma^2 \approx 1.4 \times 10^{50}$ erg s$^{-1}$. This is about 10 times the total available accretion power ($L_{\text{acc}} \approx L_{\text{disk}}$ and $L_{\text{disk}} \approx 1 \times 10^{46}$ erg s$^{-1}$; assuming radiative efficiency $\eta_{\text{disk}} \approx 10\%$). The black hole mass of 3C 279 is found in the range of $(3\sim8) \times 10^{8} M_{\odot}$ (Gu et al. 2001; Woo & Urry 2002), and thus the Eddington luminosity $L_{\text{Edd}} \approx (0.4\sim1) \times 10^{47}$ erg s$^{-1}$. Now, in order for the observed $L_{\gamma\gamma}$ to be lower than $L_{\text{Edd}}$, $\theta_{\gamma\gamma} \lesssim 3^\circ\sim7^\circ$ and a beaming factor $(1 - \cos \theta_{\gamma\gamma})^{-1} \gtrsim 240\sim440$. Similar parameters are reported by Abdou et al. (2011) for the GeV flare of 3C 454.3 during its 2010 November flare.

The cooling timescale of the $\gamma$-ray ($\epsilon_1 = 1$ GeV) emitting electrons can be calculated as follows (e.g., Saito et al. 2013):

$$\tau_{\text{cool}} \approx \frac{3m_e c}{4\pi \epsilon_0 \eta_{\text{BLR/torus}} \sqrt{c_0 (1 + z)}} \epsilon_\gamma,$$

where $\eta_{\text{BLR/torus}} = \eta_{\text{BLR}} + \eta_{\text{torus}}$, $L_{\text{disk}} = 2\pi R_{\text{disk}}^2 c$, and $\epsilon_\gamma$ is the fraction of $L_{\text{disk}}$ reprocessed by BLR/torus. This resulted in $\tau_{\text{cool}} = 7$ minutes or 11 minutes, provided that the seed photons for the EC process are originated from the BLR or torus, respectively. The obtained cooling time is significantly shorter than that observed in the decay timescale of the flares, suggesting that the observed flare decrease is controlled not only by radiative cooling, but by a combination of various factors such as the geometry and sub-structure of the emission region or possibly the jet dynamics (Tanihata et al. 2001; Kushwaha et al. 2014).

A significant break/curvature in the $\gamma$-ray spectrum is one of the characteristic properties of powerful FSRQs. Interestingly, this feature is found to be more prominent during the flaring episodes (see, e.g., Abdou et al. 2011; Paliya et al. 2015). During the P2 period, i.e., at the peak of the flare, the BPL photon index $\Gamma_1$ before $E_{\text{break}}$ ($\approx 1$ GeV) is $< 2$, thus indicating a rising spectrum, whereas $\Gamma_2 > 2$, implying a falling spectrum after $E_{\text{break}}$. This observation suggests that the peak of the IC mechanism is probably seen in the LAT bandpass, and thus the observed shape most likely reflects the energy distribution of the emitting electrons. Comparing the shape of the $\gamma$-ray spectrum with that seen during 2013 December and 2014 April reveals an interesting observation. The 2013 December flare exhibited a hard rising spectrum ($\Gamma = 1.71 \pm 0.10$; Hayashida et al. 2015) indicating that the IC mechanism peaks at very high frequencies, whereas the 2014 April events showed a steep falling spectrum ($\Gamma = 2.23 \pm 0.03$; Paliya et al. 2015), thus implying that the IC peak lies before the LAT energy range. These three flares, therefore, represent the three different characteristics of the radiative processes powering the relativistic jet of 3C 279. The observation from Fermi-LAT, in this regard, is an invaluable asset for learning the physical properties of the most powerful objects in the universe, blazars.
