We use neutron absorption in rotating $^3$He-B to heat locally a $\sim 10 \mu$m-size volume into normal phase. When the heated region cools back in $\mu$secs, vortex lines are formed. We record with NMR the number of lines as a function of superflow velocity and compare to the Kibble-Zurek theory of vortex-loop freeze-out from a random network of defects. The measurements confirm the calculated loop-size distribution and show that also the superfluid state itself forms as a patchwork of competing A and B phase blobs. This explains the A$\rightarrow$B transition in supercooled neutron-irradiated $^3$He-A.

A rapid phase transition generally leads to abundant disorder and inhomogeneity in a heterogeneous system. But even in the ideal homogeneous case, where extrinsic influence is absent, a phase transition far out of equilibrium might result in the formation of defects. This phenomenon, if shown to be true, could explain the change in the early universe from an initial homogeneous state to that at present with large-scale structure [1]. How- ever, reproducible measurements on the density and distribution of defects as a function of transition speed are experimentally a challenging task [2].

It was recently observed [3] that quantized vortices are created in superfluid $^3$He-B in one of the fastest 2nd order phase transitions probed to date. The transition is produced locally in a small volume, within the bulk medium far from boundaries, by irradiating $^3$He-B superflow with ionizing radiation. The most practical heating effect is obtained from the absorption reaction of a thermal neutron, which creates a local overheating of suitable magnitude and volume. Vortices are then found to form in increasing number per absorption reaction as a function of the superflow velocity.

Homogeneous model.—There are several possible explanations to this phenomenon. We show that a quantitative comparison can be established with the theory of defect formation in a rapidly quenched 2nd order phase transition which was proposed by Kibble [4] and Zurek [2]. In this time dependent transition the order parameter of the broken-symmetry phase begins to form independently in different spatially disconnected regions, by falling into the various degenerate minima of the Ginzburg-Landau free energy functional. Superfluid coherence is then established only locally, in causally separated regions. These grow in size with time and form defects at their boundaries when they meet an adjacent region in a different free-energy minimum.

The expected domain size of the inhomogeneity, or the characteristic length scale in the initial random network of defects, is $\xi_c = \xi_0(\tau_0/\tau_c)^{1/2}$. Here $\xi_0 \sim 20$ nm is the zero temperature superfluid coherence length, $\tau_0 \sim \xi_0/\nu_F \sim 1$ ns the order parameter relaxation time far below $T_c$, and $\nu_F$ the Fermi velocity. The deviation from equilibrium is described by the cooling rate $\tau_Q = |dT/dt|_{T=T_c}$ at $T_c$, which in our $^3$He-B experiment is $\tau_Q \sim 5 \mu$s. After the quench the defects relax, unless an external bias field is applied. In our case the superflow from rotation causes vortex loops above a critical size to escape into the bulk liquid. There the rings expand to rectilinear vortex lines, which can then be counted with NMR. The bias for the preference between $^3$He-A or $^3$He-B can be externally controlled with the choice of pressure or magnetic field.

Initial inhomogeneity.—The Kibble-Zurek (KZ) mechanism has been demonstrated to produce random networks of defects in numerical simulations [2]. It has also been compared to experiments on liquid crystals [5] and superfluid $^4$He-II [6]. However, the KZ model describes an infinite and spatially homogeneous system while any laboratory sample is of finite size with nonzero gradients. In our $^3$He-B experiment the superfluid transition moves through the rapidly cooling bubble as a phase front with a width $\sim |\nabla T|/T_{c}^{-1}$, $T_{c}$. A further important difference from the KZ model is the existence of the broken-symmetry phase outside the heated bubble. It might thus be the interface between the hot bubble (with a maximum radius $R_0 \sim 30 \mu$m) and the bulk superfluid outside which governs vortex formation.

Experiment.—The measurements are performed in a rotating nuclear demagnetization cryostat. The sample container is a quartz cylinder of radius $R = 2.5$ mm and height $L = 7$ mm [7]. While the sample is maintained at constant conditions, it is irradiated with paraffin moderated neutrons from a weak Am-Be source, to heat the fluid locally with the nuclear reaction $n + ^{3}$He $\rightarrow$ p $+ ^{3}$H $+ 764$ keV. The distance of the source from the sample is adjusted such that the observed absorption reactions are well separated in time. At constant neutron flux we record the NMR absorption as a function of time. The height of a sudden jump in the NMR absorption measures the number of new vortex lines which are formed in a neutron absorption event. Due to the large absorption cross section of the $^3$He nucleus, the mean free path of thermal
neutrons in liquid $^3$He is about 0.1 mm. Most reactions occur thus within a short distance from the side wall of the cylinder. Here the superflow velocity is $v_s = \Omega R$ with respect to the wall, when the cylinder is rotated in the vortex-free state at an angular velocity $\Omega$ \cite{12}. When a vortex line is formed $v_s$ decreases. The reduction is taken into account as described in Ref. 12. In the worst case the measuring accuracy is $\Delta v_s \approx \pm 0.04$ mm/s.

Pressure dependence.—Vortex lines are detected only if the superflow velocity exceeds a threshold $v_{cn}(T, P, H)$, which is plotted as a function of pressure $P$ and magnetic field $H$ in Fig. 1. Experimentally $v_{cn}$ is a well-defined quantity which estimates the effective radius $R_b$ of the heated bubble: The largest vortex ring, which fits into the bubble, has a diameter $D = 2R_b$. If the flow exceeds $v_s = v_{cn} \sim (\kappa/2\pi D) \ln (D/\xi)$, where $\kappa = h/2m$ is the circulation quantum and $\xi(T, P) \approx \xi_0(P) (1 - T/T_c)^{1/2}$ the coherence length, a ring oriented perpendicular to the flow expands into the bulk liquid. The pressure dependence displays an abrupt increase at about 21.2 bar, the pressure of the polycritical point: Above this pressure $P_{PCP}$ $^3$He-A is stable in zero field below $T_c$ between the normal and B phases. The measurements of $v_{cn}$ are carried out well in the B phase, but when the quench trajectory crosses the stable A-phase regime, vortex formation is reduced (trajectory (a) in the inset of Fig. 1).

Magnetic field dependence.—The parabolic dependence of $v_{cn}$ on the applied field supports the same conclusion. The only major influence of small fields on a given value of the bias field $H$ is to make $^3$He-A stable in a narrow interval from $T_c$ down to the first order AB transition at $T_{AB}(P, H)$. Thus the magnetic field lowers the A-phase energy minimum with respect to that of the B phase and again this translates to a reduced yield of vortex lines at any given value of the bias $v_s$.

Consequences.—The results in Fig. 1 contradict all attempts to explain $v_{cn}$ in terms of a superflow instability \cite{10} at the boundary of the heated bubble, which is B phase, while A phase appears only in the hotter interior. The instability should occur at the $^3$He-B pair-breaking velocity $v_s(T, P) \approx v_{cn}(P) (1 - T/T_c)^{1/2}$ \cite{10} which is exceeded at the bubble boundary, unless vortices are generated more rapidly by other means. The KZ mechanism is inherently a fast process: During rapid cooling through $T_c$ the order parameter may fall, in different causally disconnected regions, into A- or B-phase local free-energy minima. Blobs of size $\xi_v$ of A and B phase are formed, of which the former shrink away in ambient conditions, where only B phase is stable. However, it is known from experiments with a moving AB interface that the penetration of vortex lines through the phase boundary is suppressed \cite{10}. Thus we expect A-phase blobs to reduce the volume of the initial vortex network, confined within the B-phase blobs, and vortex formation is impeded.

![FIG. 1. Threshold velocity $v_{cn}$ for the onset of vortex formation in neutron-irradiated $^3$He-B superflow: (Top) The pressure dependence displays a steep change at $P_{PCP}$, although the B-phase properties do not change abruptly as function of pressure. At $P < P_{PCP}$, the curves represent $v_{cn} = (\kappa/4\pi R_b) \ln (R_b/\xi)$, where $R_b = (3/2\pi) \xi (E_0/C_m T_c)^{1/2} (1 - T/T_c)^{1/2}$ is obtained from the spherical thermal model with all of $E_0 = 764$ keV transformed to heat. The fitted scaling factor is $\epsilon = 2.1$. (Bottom) The dependence on magnetic field is parabolic and reminiscent of the equilibrium state $\Lambda \rightarrow$B transition $T_{AB}(P, H) = T_c(P) (1 - \alpha H^2)$, where $\alpha(P) \sim (0.5 - 10) \cdot 10^{-6}$ (mT)$^{-2}$ \cite{12}. (Inset) Phase diagram of $^3$He superfluids with superfluid transition at $T_c$, $\Lambda \rightarrow$B transition at $T_{AB}(0)$ in zero and at $T_{AB}(H)$ in nonzero field, and two quench trajectories (a) and (b).](image)
require (or exclude) Leggett’s inverted “baked Alaska” temperature distribution in the quench [11,13].

Velocity dependence.—Measurements of vortex-line formation as a function of superflow velocity $x = v_s/v_{cn}$; (Top) Number of lines $\hat{N}_i$ and (middle) neutron absorption events $N_e$ per minute; (bottom) number of lines per event ($\approx N_i/N_e$). All three rates have been determined independently from discontinuities in the NMR absorption as a function of time. The solid curves are fits to the expressions given in each panel.

In Fig. 2 we plot the rates $\hat{N}_i$, of vortex line formation, grouped according to the number of lines $i$ produced per absorption event per minute, plotted vs $v_s/v_{cn}$. The solid curves are guides for the eye. (Inset) Normalized threshold velocity $v_{cn}/v_{cn1}$ for the onset of an event with $i$ lines, plotted vs the number of lines $i$. The solid line represents the fit $v_{cn1}/v_{cn} = [2.0 (i - 1) + 1]^\beta$.

Simul.—The initial distribution of loops in a random vortex network with intervortex distance $\xi = \xi_v$ can be established with a standard simulation calculation [15,16]. We use a “cubic bubble” which is subdivided into a grid of size $\xi$, with up to $200^3$ vertices. A random phase is assigned to each vertex initially, to model the randomly inhomogeneous order parameter. On the boundary of the bubble the phase is fixed, to ensure that no open-ended loops are formed. The results have been checked by averaging over up to 10,000 different initial configurations. We use a continuous phase variable rather than restricting it to some set of allowed values. The
distribution of the phase is extended to the edges of the grid according to the shortest path on the phase circle. Line defects are positioned to cross through the center of those grid faces for which the phase winding is nonzero.

As usual, we assume that the initial loop distribution is preserved during the later evolution of the network in 15, when the average intervortex distance $\xi(t)$ increases, but the network remains scale invariant, independently of the momentary value of $\xi(t)$. Two scaling relations of standard form are found to hold for the networks:

$$n(l) = Ct^{-\beta}, \quad (C \approx 0.29, \quad \beta \approx 2.3) \quad (1)$$

$$D(l) = A t^\delta, \quad (A \approx 0.93, \quad \delta \approx 0.47) \quad (2)$$

where we put $\xi = 1$, $l$ and $D$ are the length and average straight size diameter, and $n(l)$ the density of loops with length $l$. The numerical values of the parameters depend slightly on the size of the bubble, due to boundary conditions, but in the limit of a large bubble they are close to those obtained for networks with mostly open-ended strings 14, 15. For a Brownian walk in infinite space the values of $\beta$ and $\delta$ are $5/2$ and $1/2$.

Vortex loop escape.—The energy of a loop is

$$E(l, S, t) = \rho_s k \left[ \frac{l}{4\pi} \ln \frac{\xi(t)}{\xi} - v_s S \right], \quad (3)$$

where $S$ is the algebraic area of the loop in the plane perpendicular to the direction of the superflow at $v_s$. A new result from our simulation is a scaling law for $S$:

$$|S| = B D^{2-\nu}, \quad (B \approx 0.14, \quad \nu \approx 0) \quad (4)$$

Using Eq. (3) for $l(D)$ one has for a loop with $S > 0$

$$E(D, t) = \rho_s k D^2 \left[ \frac{\kappa}{4\pi \xi(t) A^2} \ln \frac{\xi(t)}{\xi} - v_s B \right]. \quad (5)$$

When the mean diameter of curvature $\xi(t)$ exceeds the critical value, $\xi_c(v_s) = (1/A^2 B) (\kappa/4\pi v_s) \ln \xi$, the energy becomes negative. Analytically we obtain the number of loops extracted per neutron from $N_i = V_b \int_0^{2R_b} dD n(D)$, where $\xi_c(v_s = v_{cn}) = 2R_b$ defines the threshold velocity. This result is only a function of the relative velocity $x = v_s/v_{cn}$ and reproduces the measured dependence in Fig. 2. $N_r \propto x^3 - 1$. An event with $i$ rings becomes possible, when $N_r \sim i$. This gives for its threshold velocity $v_{cnt} = v_{cn}$ and $v_{cnt} = 1^{1/3}$, as measured in Fig. 3.

In the simulation, loop escape is modelled by setting the grid size $\xi$ to correspond to integer values of $x = i$. A tangled loop, projected in the plane perpendicular to $v_s$, is represented as a sum of elementary loops of grid size. The number of escaping loops $N_{rt}$ is assumed to be the total number of positive elementary loops. The results in Figs. 4 and 8 are obtained without fitting parameters.

The scaling calculation is justified in so far that the later evolution of the network is orders of magnitude slower than $\tau_0$. Thus the latter is taken into account separately with a calculation of the vortex dynamics 16, including mutual friction and the polarization of the vortex tangle by the superflow. We have performed preliminary calculations on small lattices (up to $40 \times 40 \times 40$) and find that even close to $T_c$ the scaling law (3) remains valid at larger loop lengths $l > 4\xi$ and that the result for $N_t(v_s/v_{cn})$ does not change qualitatively.

Conclusion.—We have established quantitative agreement between measurement and the KZ mechanism. When the 2nd order phase transition moves at high velocity into the volume heated by the neutron absorption, a random network of different types of defects is formed. This happens before other mechanisms, such as a superflow instability at the boundary of the rapidly cooling bubble or superfluid turbulence within its interior, have a chance to develop. A bias field of sufficient magnitude will select the type of defect, which remains stable while others relax. In superflow these are vortex loops. In supercooled $^3$He-A it is blobs of $^3$He-B, which have a finite probability to start the A$\rightarrow$B transition.
