\textbf{ABSTRACT}

Plants response to symbiosis with arbuscular mycorrhizal fungi (AMF) under water stress is important to agriculture. Under abiotic stress conditions native fungi are more effective than exotics in improving plant growth and water status. Mycorrhization efficiency is related to soil fungi development and energy cost-benefit ratio. In this study, we assessed the effect on growth, water status and energy metabolism of Cucurbita pepo var. pepo when inoculated with native AMF from the Sonoran desert Mexico (mixed isolate and field consortium), and compared with an exotic species from a temperate region, under drought, low and high salinity conditions. Dry weights, leaf water content, water and osmotic potentials, construction costs, photochemistry and mycorrhization features were quantified. Under drought and low salinity conditions, the mixed isolate increased plant growth and leaf water content. Leaf water potential was increased only by the field consortium under drought conditions (0.5–0.9 MPa). Under high salinity, the field consortium increased aerial dry weight (more than 1 g) and osmotic potential (0.54 MPa), as compared to non-mycorrhized controls. Plants inoculated with native AMF, which supposedly diminish the effects of stress, exhibited lower construction costs, increased photochemical capacity, and grew larger external mycelia in comparison to the exotic inoculum.

\textbf{Introduction}

Aquifer over exploitation in semi-arid agricultural regions has increased soil salinity and caused water shortage.\textsuperscript{3} The direct effect of such increasing soil salinity on production has been documented in the coastal region of Hermosillo, Mexico.\textsuperscript{7} One of the proposals for mitigating these negative effects is the use of biofertilizers based on arbuscular mycorrhizal fungi (AMF), given that mycorrhizic symbiosis improves the establishment,
vigor, productivity and survival of plants under water stress and salinity.2,4

The beneficial effects of AMF on plant development and soil features are considered relevant for sustainable agricultural management. However, conventional agriculture practices affect AMF diversity and density.5 Currently, isolated fungi species are used to colonize a wide variety of commercially important vegetables. Nonetheless, special interest has been given to characterization of native AMF species, since they are considered to be more efficient inoculates under environmental conditions similar to their origin, in contrast to exotic fungi from different environments.6

Since plant-AMF establish a compelled symbiosis, host responses to mycorrhization depend on the interaction efficiency between the symbionts, which in physiological terms is related to the amount of nutrients acquired by the host by unit of carbohydrates spent in supporting the guest. A study reporting the mycorrhization effect of Glomales on physiological and nutritional responses by several hosts found that water stress host tolerance varied depending on the associated AMF,3 and some fungi even diminished salinity and drought injuries.7,8

Ecophysiological studies found that mycorrhized plants response is better when accomplished by native strains. Apparently, this phenomenon is related to the fungi’s environmental sensitivity and to external mycelia development, which modifies water retention soil capacity and host water relations.9,10

Given the chemical composition of a plant, it is possible to estimate construction costs, defined as the total amount of photo-assimilates used for the construction of a gram of plant tissue, which is considered a useful measurement for evaluating plant development.11 Symbiosis may indirectly stimulate carbon fixation, eliminating symbiosis related costs in the plant energy budget providing a real benefit for both parts.12 Although the daily carbon flux between plant and fungus does not change, the final costs vary in relation to characteristics unique to each association. The resources efficient assimilation and the optimal biomass partition are determinant to the competitive ability and, in many cases, tolerance to stress conditions by hosts.13

One way of assessing the physiological response of mycorrhized plants subjected to stress is by measuring photosynthesis and chlorophyll fluorescence. Pinier et al.14 found that mycorrhization with Rhizophagus intraradices (N.C. Schenck and G.S. Sm.) C. Walker and A. Schüßler increased the tolerance of Rosa hybrid L. to water stress by increasing its photosynthetic activity, specifically in electron transport in photosystems I and II. Chlorophyll-a fluorescence analysis allowed the evaluation of AMF influence in reintroduced plants during their acclimation by quantifying the conservation of photosynthetic energy.15

Since it is possible to establish mycorrhization effects by evaluating host through assessing the photosynthetic and metabolic energies, in this work we evaluated some of the physiological responses to drought and salinity stresses in Cucurbita pepo var. pepo mycorrhized with native fungi from the Sonoran desert, with the objective of relating such changes in energy metabolism with a possible reduction of injuries caused by those stresses. Differences in plant growth and water status depend on the inoculum geographic origin. Mycorrhization with native organisms adapted to the stressing conditions improves cost-benefit ratio of association.

Materials and methods

Isolation of inoculates

Two native AMF treatments were used in this study, a mixed isolate (MI) with two types of spores: Glomus sp. 1 (42 spores g⁻¹) and Glomus sp. 4 (24 spores g⁻¹), as well as a field consortium (FC) with seven types of spores: Glomus sp. 1 (103 spores g⁻¹), Claridoeglomus claroideum (N.C. Schenck and G.S. Sm.) C. Walker and A. Schüßler (90 spores g⁻¹), R. intraradices (34 spores g⁻¹), Pacispora sp. 1 (27 spores g⁻¹), Glomus sp. 3 (11 spores g⁻¹), Glomus sp. 4 (10 spores g⁻¹), Pacispora sp. 2 (7 spores g⁻¹). AMF were selected from 9 abandoned fields in La Costa de Hermosillo (LCH), Sonora (28°35’–28°50’ N, 111°15’–111°35’ W). Field soils had salinity of 0.9 up to 5.2 DSm⁻¹, pH 8, sodium adsorption ratio of 3, exchangeable sodium percentage of 3.5 and 70% of sand; dominated by Atriplex canescens (Pursh) Nutt., Baccharis sarothroides A. Gray, and Encelia farinosa A. Gray ex Torr. The seven most frequently isolated AMF were included in this study. In order to increase the number of MI spores, Sorghum bicolor L. was cultivated with Glomus sp. 1 and 4, and for FC spores by cultivating C. pepo var. pepo in soil samples from LCH, obtaining an inoculum comprised of seven morphospecies of AMF.

Culture conditions and inoculate treatments

Five seeds of C. pepo var. pepo were planted in 5 L pots with a sterile substrate (5:2 peat moss: soil). Plants were grown under natural lighting until flowering, at 26.5% relative humidity and 24 °C. For each treatment, 6 replicates were made, keeping three plants per pot. In all experiments, inoculation was performed 10 d after planting, and treatments were established by inoculating hosts as follow: Inoculation of each plant with 3 g of mixed isolate of native AMF (treatment MI), and 1.5 g of the field consortium (FC). A third treatment was an exotic species, 1 g of C. claroideum, from a temperate region of Central Mexico from Hueytolipan, Tlaxcala (treatment EJ). This strain was not included in FC. Negative controls for each stress treatment consisted in plants without AMF which received 1 g of sterile soil as inoculate (treatment C).

Stress by drought and salinity

Experiments to evaluate mycorrhization effects on plant responses to drought and salinity exposure were executed by separate. The first experiment was run for 57 d and evaluated the effects of drought and AMF inoculation on C. pepo var. pepo. While the second experiment dealt with responses to high and low salinity and lasted 47 d. Assessment of drought effects took place in the summer, while salinity experiments were carried out in the fall. Plants subjected to drought stress were irrigated with 25–50 mL per day (soil humidity of 25–40%). Soil moisture was determined gravimetrically. Low salinity stress was created by irrigating plants with a 40 mM NaCl solution, maintaining a salinity of 3.8 ± 1.2 DSm⁻¹. High salinity was
achieved by irrigation with a 50 mM NaCl solution to maintain
a mean salinity of 4.5 dS m⁻¹ (3.5–6 dS m⁻¹). Salinity was
measured based on samples electrical conductivity values
according to Shirokova et al. Non-stressed (no drought,
neither salinity) controls, were irrigated with 100 mL of water
per day (soil moisture content of 50–60% and 1.4 ± 0.4 dS m⁻¹).

Response assessment

Total dry weights (both aerial and radicular) were measured
by drying soil debris-free plant material in a lab oven (Blue
M Stabil-Therm, model D-5226-Q, Evansville, IN, USA) at 60 °C
for 72 h. Leaf water content was quantified by the difference
between leaf sections fresh and dry weights and expressed on
a percentage basis. Water potential (Ψw) was quantified with
a Scholander pump (PMS Instrument Co., Albany, OR, USA).
Samples were frozen at −80 °C to obtain the intracellular exu-
date of the foliar tissue and then measure their osmolarity (Ci,
mmol/kg) with an osmometer (Wescor Vapor 5520, Logan, UT,
USA). Results of osmolarity were converted to osmotic poten-
tial (Ψs) through the Van’T Hoff equation: Ψs = −CiRT, where
Ci refers to osmolarity, R gas constant and T to temperature
(°K).

To estimate construction costs, leaves were harvested from
every plant on each treatment and dried at 60 °C for 24 h. Glu-
cose was estimated from the amount of carbon and energy
required for tissue construction (g glucose g⁻¹ dry weight) by
measuring the combustion heat (ΔHc) with a Parr calori-
rometer pump (model 1341, Moline, IL, USA), the ashes (A) in a muffle
furnace (Thermolyne type, model 30400, New York, NY, USA),
and nitrogen content (N) (LECO PF-528, St. Joseph, MI, USA).
Resulting values were used to estimate the construction costs
(CC) according to Carey et al.:

\[
CC = \frac{(0.06968 \Delta Hc - 0.065) (1 - A) + 0.5359 kN}{E_G}
\]

where \(k\) is the oxidation state of the nitrogenized substrate
(ranging from +5 nitrates to +3 ammonium) and \(E_G\) is the con-
version efficiency (0.89).

Chlorophyll fluorescence was measured at 25–28 °C with a
Handy PEA fluorimeter (Hansatech Instruments Ltd., King’s
Lynn, NO, England) equipped with a three high-intensity light
emitting diode array at an excitation wavelength of 650 nm
and an emission wavelength range of 680–750 nm, over a foliar
surface of 4 mm in diam. Readings were taken at 0.05, 0.1, 0.3,
2, and 30 mm on the third leaf from the meristem after keeping
the measured leaf section in absence of light for 30 min.

Evaluated variables included basal fluorescence intensity
\(F_0\), maximum fluorescence intensity \(F_{Mn}\), and time to reach
maximum fluorescence \(T_{\text{max}}\). These values were used to
estimate the absorbed-electron flux per surface unit index
(ABS/CS), the excitons canalized to the reaction center per
surface unit index (Tro/CS), and the amount of electrons
transferred to the electron transport chain for estimation of
chemical energy (E10/CS). Based on these values, the per-
formance index (PI) was calculated using the equation, through
the Handy PEA 32 bit Windows® software, as in Strasserf
et al.:
and radicular dry weight (RDW) were similar when comparing the results obtained for non-inoculated controls and the different AMF inoculates (MI, FC and EI).

After 57 d of culture with irrigated treatment, changes in some variables related to the plant water status were observed when comparing C with the AMF inoculated treatments. A 0.7% decline in foliar water content was detected for MI, 0.33 vs. 0.6 MPa in ψs for EI and FC respectively. Also, the construction cost was less for FC (0.12 g of glucose g⁻¹ of foliar weight) compared with C. In the 47 d cultures with normal salinity, the water status of AMF inoculated plants was similar and the construction cost was equal or larger (0.02 g of glucose g⁻¹ of dry weight) for EI with respect to C, except for MI, where ψw increased in 0.9 MPa and construction costs declined in 0.08 g of glucose g⁻¹ of dry weight (Table 2).

When stress by drought and inoculation with native AMF was applied (MI and FC), constructions costs were similar to C (Table 1). MI increased in ADW (1 g), foliar water content (4.5%) and ψw (0.55 MPa) in relation to C. Minor increases were detected for FC, 0.6 g in ADW, 3.6% in foliar water content and 0.38 MPa in ψw, without decrease in ψs. With the exotic species no differences were observed in most of the evaluated variables vs. C, except for the construction costs where an increase took place in EI (>0.03 g of glucose g⁻¹ of dry weight compared to C).

When low-salinity stress was applied (Table 2), the inoculates composed by native AMF (treatments MI and FC) produced an increase in ADW, A-R and foliar water content of the plants. On the other side, construction cost did not change with MI, while with FC it was 0.04 g of glucose g⁻¹ of dry weight more in relation to C. Under low-salinity stress, a larger benefit was observed in the increase of plant growth with the mixed native AMF inoculate in comparison to C (3 g of ADW and 15 units of A-R with MI in comparison to 2.5 g of ADW and 10 units of A-R quantified in FC). Foliar water content was improved with FC (5.7%), while with MI the difference was of 4.1%. In treatment EI, an increase of 0.9 g of glucose g⁻¹ dry weight in construction cost was observed in respect to C, however, no statistically significant differences were observed in growth and water status.

Under high-salinity, construction costs associated with FC was significantly higher than C (0.05 g of glucose g⁻¹ of dry weight). Compared to C, plants inoculated with FC increased 0.9 g of ADW, 36 units of A-R and radicular growth diminished (0.3 g); while MI and C were similar in RDW, AR, ψs, and CC (Table 3).

The mycorrhization features for native inoculates were compared to those quantified with EI. It was observed that after 57 d without stress applied, the external mycelia were similar, while the percentage of MC and TNS was significantly lower for MI and FC with respect to EI. On the other hand, after 47 d in culture, the external mycelia for MI and FC was 10 mg g⁻¹ of soil less than in EI; MC was similar between all individuals and TNS only increased by 50 spores per 10 g⁻¹ of soil with FC vs. EI (Table 4).

Under the three evaluated stress conditions, native AMF inoculates (MI and FC) presented a significantly higher growth of external mycelia (10–20 mg g⁻¹ of soil) than EI, at the high-salinity treatment a difference higher than 20 mg g⁻¹ of soil was found (Table 3). MC under drought conditions was similar between inoculates (Table 4), while salinity diminished the values for this variable with respect to EI, being 30% lower with native AMF (low-salinity treatment) and only 10% lower with MI (high-salinity treatment) (Table 4).

Fig. 1 shows differences in performance index (PI) between inoculation treatments were observed at day 45. The intervals for PI values were different between experiments for assessing drought (1–4 units), low salinity (0.3–1 units) and high-salinity (2–8 units). No significant differences were found among the different inoculation treatments under non-stressed conditions (Fig. 1B and D).

Performance index for C. pepo var. pepo applying drought is shown in Fig. 1A; when plants were treated with MI and FC, this index was higher than 3 units and significantly higher than EI (2.2 units) and C (1.8 units) after 45 d. Under low-salinity conditions (Fig. 1C), plants inoculated with native

These values correspond to the mean ± standard error of the results for the mixed inocula (MI), field consortium (FC), exotic inocula (EI) and control (C). Factorial analysis *significance $p \leq 0.05$ among the stress treatment (drought or low salinity) and mycorrhization (M).
fungi exhibited a PI higher than 0.6 units and higher than EI (0.35 units), while the lowest value was measured for C (0.28 units). For cultures under high-salinity stress, the highest PI was detected for treatment FC (7.8 units), while this value was similar among cultures treated with MI and C (4–5 units) and higher in relation to plants treated with EI (2.21 units).

Table 5 shows the differences in spore content by morphospecies of native AMF inoculated on C. pepo var. pepo under conditions of stress by drought, low and high salinity, and non-stressed. When inoculating MI, regardless of stress condition, spore composition was Glomus sp. 1 and Glomus sp. 4 ranging from 80.2 to 89 and 11 to 19.8% respectively.

FC inoculated plants subjected to water stress yielded spores from only four morphospecies; according to their prevalence and in descending order, those were: Glomus sp. 1 > Glomus sp. 4 > Pacispora sp. > C. claroideum (Table 5). Under low salinity, a value of 47.1% was quantified for Glomus sp. 1, 28% for C. claroideum, 18.5% for Glomus sp. 3 and finally, 3.2% for Pacispora sp. and Glomus sp. 4. On the other hand, under high salinity conditions, 6 of the 7 inoculated morphospecies were found in the sporeulate form. The lowest sporulation was found for Pacispora sp. (1.4%) and Glomus sp. 3 (4.6%); while the highest values corresponded to Glomus sp. 1 (56.2%). In all abiotic stress conditions, Glomus sp. 1 resulted in the highest spore count when plants were inoculated with FC.

Discussion

Previous ecological and agronomical studies demonstrated how plant-AMF associations mitigate the damaging effects caused by water scarcity and soil salinity, improving plant growth and water status in several species, in contrast with non-mycorrhized plants under equal stressing conditions. However, plant response to stress may also vary depending on the fungi species. This study showed that symbiosis efficiency differed in relation to the inoculate composition and the origin of the AMF used. Under drought and salinity conditions, the dry weight and leaf water content of plants inoculated with an AMF species from a temperate region (EI) were similar to non-inoculated controls, while those inoculated with native AMF (MI and FC) did improved growth and water status (Tables 1 and 2).

Soil properties affect mycelium extension rate in several ways, since some AMF species are more susceptible to drought and saline conditions. The stress conditions assessed in this study reduced C. claroideum extracellular growth in comparison to the native species used as inoculum, since under

Fig. 1 – Performance index (PI) assessed at 21, 27, 38 and 45 d in culture and calculated through readings of chlorophyll fluorescence in Cucurbita pepo var. pepo under conditions of drought (A), irrigated (B), low salinity (C), normal salinity (D), and high salinity (E). These values are the arithmetic mean for three replicates, vertical lines represent standard deviation. Treatment C (----), treatment EI (----), treatment FC (-----), treatment MI (-----). Symbols for each inoculation treatment are the same as in Table 1.
drought and salinity, the amount of mycelia produced by MI and FC was over 50% highest (Tables 3 and 4).

Beneficial effects of mycorrhization with native AMF in growth and water status of C. pepo var. pepo can be related to the high external mycelia growth in MI and FC. A similar response was described in Phaseolus vulgaris and Lactuca sativa grown under water stress, because a direct relationship was established between the greatest increases in biomass, soil water potential, and leaf lethal water potential with those AMF producing the largest extracellular mycelia.22,23

Salts and changes in water availability modify mycorrhizal colonization.25 Largest mycorrhizal colonization in Citrus tangerine resulted in improved dry weight and relative water content when plants were grown under drought.7 Our results are in agreement since the inoculants that mitigated drought negative effects (MI and FC) produced larger root mycorrhization than exotic inoculants (EI), which did not improve neither growth, nor plant water status.

In contrast to observations under drought, with high and low salinity the colonization percentage is smaller with the more effective treatments (Tables 3 and 4). However this does not agree with reports in Lactuca sativa grown under saline stress, where the most beneficial AMF species showed the highest colonization.5 Plants inoculated with native AMF (MI and FC) and grown under drought or low salinity showed a significant increase in growth and water status, maintaining tissue construction costs similar or lower than those of non-inoculated plants (Tables 1 and 2). In a previous study with C. pepo grown under drought conditions, mycorrhization with R. intraradices improved stomata conductance and water potential gradient when water-loss rates varied by transpiration, while gas exchange increased to compensate for the additional carbon transferred to fungus.26

Performance index calculations, based in chlorophyll fluorescence readings, are measurements of plant relative vitality.19 Plant photochemistry assessment is a good indicator of its photoprotection under stress conditions,27 additionally this sort of assessment has been done to evaluate vitality in mycorrhized plants in terms of energy use efficiency during molecule biosynthesis.14,15 This study shows that the inoculation of native AMF (MI and FC) increased PI in comparison to non-inoculated cultures and in relation to C and EI treatments, mostly under low salinity. Abo-Ghaila and Khalafallah25 found that, mycorrhization of Triticum aestivum under drought improved photosynthetic rates and increased carotenoid pigments and chlorophyll to counteract against photodestruction or photoinhibition.

Differences in intervals, including PI, in experiments 1 (drought assessment) and 2 (low salinity assessment) might have affected by changes in light intensity and temperature, given that experiments took place in different seasons. These differences have been previously documented in other plant species submitted to light and temperature stress.28

Mycorrhization implicates an increase in plant energy costs, however several studies prove that construction costs (CC) are lower when AMF improve efficiency in nutrient usage as well as the organism’s adaptation to environmental conditions.29 In this case, the negative effects of drought and salinity over growth and water status are smaller when plants are mycorrhized by native fungi (Tables 1 and 2). The greatest benefit was obtained from MI and FC, where CC were similar or lower than C, while their PI’s were highest.

The benefits given by AMF in terms of nutrition and water use efficiency compensate the energy expenditure implied in the transference of photoassimilates to the fungus.30 MI was most effective under stress by low salinity and drought, while FC was more effective under high salinity conditions. Additionally, there was an increased efficiency in the photochemistry capacity (measured through PI) in plants mycorrhized with native fungi, which suggests a compensation for the energy expend and carbon transference to the fungus. Thus tissue CC is similar or lower to those of plants associated with less effective AMF (EI).

Saline conditions either destroy PSII reaction centers or interrupt electron transference,31 such effects are mitigated when plants are associated with AMF by increasing chlorophyll content and photosynthetic capacity with respect to non-mycorrhized cultures.32,33 Changes in photosynthetic capacity are related to water status and gas exchange34 and also to electron transport capacity. In this study, under high salinity conditions, the greatest increase in PI was observed in those cultures grown in substrates inoculated with FC, which

| Morphospecies | Spore content (%) |
|---------------|-------------------|
|               | Drought            | Salinity         |
|               | Non-stressed       | Stressed         | Non-stressed | Low | High  |
|               | MI  | FC | MI  | FC | MI  | FC | MI  | FC | MI  | FC |
| C. claroideum  | 23.1 | 2.7 | 21.5 | 28.0 | 14.1 |
| G. intraradices| 5.5  |     | 0.4  |     |     |
| Glomus sp. 1  | 87.0 | 54.5 | 81.9 | 60.5 | 47.1 | 56.2 |
| Glomus sp. 2  | 1.2  |     | 2.7  |     | 18.5 |     |
| Glomus sp. 3  | 2.2  |     | 5.6  |     | 3.2  | 1.4 |
| Glomus sp. 4  | 13.0 | 10.4 | 14.3 | 4.8  | 3.2  | 1.4 |
| Pacispora sp. 1| 0.9 |     | 3.3  |     | 3.2  | 1.4 |
| Pacispora sp. 2| 2.2 |     | 6.0  |     | 9.0  |     |

Spore content (%) was calculated based on the sum of spores (total and per species) of six replicates. Captions for each inoculation treatment are as in Table 1.
exhibited less damage by salts, allowing to the conservation of CC similar to non-mycorrhized plants and implying a similar efficiency to the non-stressed negative control (Table 3, Fig. 1E). Even though the AMF-plant interaction is slightly specific, there are biochemical characteristics involved with the plant-fungus association function, which modify the success of the symbiosis.\textsuperscript{5} Even there are AMF ecotypes better adapted to certain environmental conditions.\textsuperscript{10,24} In the native inoculates (MI and FC), *Glomus* sp. 1 demonstrated to be most efficient in sporulation, despite all the assessed conditions. Thus, it is considered that this species associates better with *C. pepo* var. *pepo* and is adapted to the assessed stress conditions.

Also, some of the morphospecies initially present in FC showed no sporulation under drought or salinity stresses (Table 5). The variations in AMF diversity observed in these experiments were similar to those found in wheat inoculated with a mixed isolate of *Glomus* spp. under stress by drought, in which species diversity decreased as water availability abated.\textsuperscript{25}

**Conclusion**

AMF native from the Sonoran Desert mitigated the harmful effects of stress by drought and salinity on growth and water status of *C. pepo* var. *pepo* in comparison with *C. claroideum* native from a temperate region. The mixed inoculate MI, composed of two morphospecies of native AMF was the most beneficial under conditions of drought or low salinity. Under high salinity, the field consortium composed of 7 morphospecies of native AMF (FC) resulted better for plant adaptation to this stress condition. Benefits were related to the high amounts of external mycelia quantified in the soil, low CC, and to an increase of photochemical capacity measured as PI.
