Abstract
Nephron-sparing surgery (NSS) is the standard of care for the management of localized renal tumors. A significant number of patients develop acute kidney injury (AKI) following NSS with potential long-term effect on renal function, and eventually overall survival. The aim of the current study was to assess the long-term functional impact of AKI in patients undergoing NSS. From our NSS cohort, we analyzed the clinical and surgical data of patients treated with NSS. Renal function was assessed using serum Creatinine (sCr) and estimated glomerular filtration rate (eGFR) was estimated using the MDRD equation. SCr was assessed daily starting one day before surgery until discharge. AKI was defined using the latest definition by KDIGO (Kidney Disease: Improving Global Outcomes). Appropriate statistical tests were used to compare between both groups. Of 236 patients, 86 (36.4%) developed AKI. The vast majority of patients (n = 79) displayed grade I AKI, six had grade II and only one patient had grade III. Mean baseline sCr of the AKI group was 1.11 ± 0.43 mg/dL (median 1.0, range 0.5-3.0), and their long-term mean sCr was 1.4 ± 0.6 mg/dL (median 1.2, range 0.6-1-4.5). Median follow-up time was 4 years. Most patients (79%) of the AKI group showed improvement in renal function compared with the immediate post-operative level. However, eighteen patients (21%) demonstrated stable or deteriorating renal function. The mean difference between last available sCr and baseline sCr in the improved group was 0.12 mg/dL compared to 0.87 mg/dL in the deteriorating group (p = 0.0001). The only statistically significant difference between patients who improved their sCr and patients who did not, was hypertension at diagnosis (p = 0.02).

2. Patients and Methods
Our NSS database includes clinical, surgical and oncological parameters on 464 patients since 2000 [7]. For this study, we included all 236 adult patients with complete baseline and long-term data. Patients were grouped as either AKI or non-AKI, based on the latest definition by KDIGO [9], which is based on the AKIN [10] and RIFLE [11] criteria. We then sub-grouped the AKI patients into three grades based on the same criteria.

Renal function was assessed the day before surgery, on the day of surgery, and daily thereafter until discharge (usually on post-operative day 3). Patients were treated with open NSS using a flank approach as we previously described in detail [12].

Parametric variables were compared using t-test. Non-parametric variables were compared by Chi-square test or Fisher’s exact test as needed. Multivariate linear logistic regression analysis was performed to control for confounding variables. Two tailed P value of ≤ 0.05
were performed using SPSS v23 software.

Table 1. Baseline characteristics and surgical data of both study groups.

| Parameter                        | AKI (n = 86) | Non-AKI (n = 150) | P-value |
|----------------------------------|--------------|-------------------|---------|
| Age (years), mean ± SD           | 61.6 ± 13.0  | 60.7 ± 11.7       | 0.5     |
| Sex, no. (%)                     |              |                   | 0.002   |
| Male                             | 73 (84.9)    | 99 (66.0)         |         |
| Female                           | 13 (15.1)    | 51 (34.0)         |         |
| Hypertension, no. (%)            | 56 (65.1)    | 86 (57.3)         | 0.3     |
| Smoking, no. (%)                 | 44 (51.1)    | 87 (58.0)         | 0.3     |
| Alcohol, no. (%)                 | 31 (36.0)    | 48 (32.0)         | 0.5     |
| BMI (kg/m²), mean ± SD           | 29.2 ± 4.7   | 28.3 ± 4.4        | 0.2     |
| Tumor size (cm), mean ± SD       | 4.3 ± 1.8    | 4.2 ± 1.7         | 0.6     |
| Renal score                      | 8.2 ± 1.8    | 8.0 ± 1.8         | 0.3     |
| Side, no. (%)                    |              |                   | 0.6     |
| Right                            | 37 (43.0)    | 60 (40.0)         |         |

BMI: body mass index; sCr: serum Creatinine; eGFR: estimated glomerular filtration rate; N/A: not available; RCC: Renal cell carcinoma; EBL: estimated blood loss. Significant P-values are shown in bold.

3. Results

AKI was documented in 86 (36.4%) patients out of 150 patients included in this study who did not have any significant change in renal function following surgery. Table 1 shows that the baseline characteristics of the AKI and non-AKI groups were comparable in most, but not all, parameters. The AKI group had higher percentage of male patients (81.7% compared to 67.1%, p = 0.01). Some surgical parameters favored the non-AKI group; namely, shorter ischemia time (23.7 vs 28.2 min, p = 0.004), less intra-operative blood loss (85 vs 190 cc, p = 0.047) and less blood transfusion (2.0% vs 8.1%, p = 0.046). Another clinically significant difference between the studied groups was the higher rate of tumor bed closure by sutures rather than tissue adhesive (48.8% vs 27.3%, p = 0.004) in patients with post-operative AKI. Regarding baseline renal function, the AKI group had a slightly higher mean baseline sCr (as shown in Table 2) but not eGFR. As expected, the mean sCr and eGFR at last available follow-up was significantly in favor of the non-AKI group (1.0 ± 0.36 mg/dL vs 1.39 ± 0.59 mg/dL, p = 0.0001 and 77.9 ± 20.5 ml/min vs 60.5 ± 23.5 ml/min, p = 0.0001, respectively). Moreover, a 5-fold decrease in the mean sCr level at last follow up compared with baseline level was noted in the AKI group (0.29 mg/dL vs 0.04 mg/dL). Similarly, the average $\Delta$ eGFR was nearly 4-fold lower than that of the non-AKI patients (4 ml/min vs 15.2 ml/min). Multivariate regression analysis showed that ischemia time, male gender and baseline sCr were the most significant risk factors for the development of post-operative AKI.

The vast majority (n = 79) of the AKI patients had grade I AKI (highest post-operative sCr less than double the baseline sCr and < 25% decrease in eGFR). Only a single patient displayed grade III AKI (> 75% decrease in eGFR or > 3x baseline sCr), and 6 patients had grade II injury. Table 2 shows that patients who exhibited grade II-III kidney injury had higher sCr at last follow-up compared to baseline levels (mean 1.66 vs 1.36 mg/dL, median 1.7 vs 1 mg/dL). By contrast, mean last sCr in patients who had grade I injury was 1.33 mg/dL compared to 1.06 mg/dL at baseline (median 1.18 vs 1.0 mg/dL). As expected, the deterioration of sCr and eGFR were more prominent in patients with grade II-III AKI (Δ 0.7 vs Δ 0.2 mg/dL and Δ 38 vs Δ 16 ml/min, respectively). Univariate and multivariate analysis did not show any demographic, clinical or surgical differences between patients who developed grade II or III injury compared to patients who developed grade I injury (data not shown).

4. Discussion

The most important advantage of partial nephrectomy over radical nephrectomy, which crowned the former as the gold standard treatment for localized renal masses, is the preservation of renal function [1, 2]. Huang et al., showed 20% progression to chronic kidney disease (CKD) among patients who underwent NSS compared to 65% among patients who have undergone radical nephrectomy [13]. Therefore, AKI occurring after NSS, with a potential impact on the long-term renal function, could be devastating.

In the medical literature, AKI is clearly defined [9–11]; however, AKI definition following NSS is not uniform; as such, different authors have used various definitions to report its incidence, and the inevitable result is large differences in the reported incidence of post-operative AKI. In the current study, we used the medical definition of AKI based on the KDIGO definition [9], which is mainly based on sCr. Based on these criteria, 36.4% of the patients who underwent
They also reported the incidence of AKI using very strict criteria and analysis starting several hours after surgery (post-operative day 0) until NSS developed AKI that was diagnosed by using consecutive sCr analysis. Patients who developed AKI showed 20% increase in sCr on the long-term follow-up, and 22% decrease in eGFR. Of this group, those who developed grade II-III AKI showed the highest impact on long-term renal function with 70% increase in mean sCr and 40% decrease in eGFR.

The data presented in the current study indicate that development of immediate post-operative AKI has long-term effect on renal function, especially in patients who develop a high-grade AKI. This raises the question who are the patients that are more prone to develop AKI and how can one reduce its incidence or limit its long-term deleterious effect on kidney function. In a previous study, we showed that male gender, history of nephrolithiasis, low baseline eGFR, smoking and hypertension were the most significant and independent comorbidities associated with AKI following NSS [7]. Additional risk factors for the occurrence of AKI include: higher pre-operative sCr, higher intra-operative blood loss and subsequent blood transfusion, closing the tumor bed with sutures rather than with glue and longer ischemia time [8, 15].

The most important limitation of our study is its retrospective nature, which precluded our ability to analyze our entire database, as some patients were lost to follow-up. Being a single-center study has results do not necessarily represent other institutions which are utilizing some surgical technique. Lastly, a prospective, multicenter larger study could better define the long-term functional implications of AKI after NSS.

### 5. Conclusions

A relatively high number of patients develop AKI following NSS based on its clinical definition. Fortunately, most of the patients develop low-grade AKI. Patients who develop AKI set a new sCr “baseline”, which is in average, 25% higher than the pre-operative sCr level. Patients who develop high-grade AKI are more prone to deteriorating renal function during follow-up.

### Table 2. Renal function assessment in the whole cohort and the subgroups.

| Parameter          | All (n = 236) | AKI (n = 86) | Non-AKI (n = 150) | P-value |
|--------------------|---------------|--------------|-------------------|---------|
| Baseline sCr       | 1.01 ± 0.3    | 1.1 ± 0.4    | 1.09 ± 0.4        | 0.96 ± 0.2 | 0.03 |
| Mean ± SD          | 0.97          | 1.0          | 1.0               | 1.0     | 0.95 |
| Median             | 78.5 ± 21.1   | 75.7 ± 23.5  | 76.1 ± 22.1       | 80.2 ± 19.5 | 0.1 |
| Baseline eGFR      | 79            | 77.0         | 77.0              | 80.0    | |
| Mean ± SD          | 1.2 ± 0.5     | 1.6 ± 0.6    | 1.56 ± 0.47       | 2.6 ± 0.98 | 0.0001 |
| Median             | 1.1           | 1.5          | 1.5               | 2.4     | 1.0 |
| Worst post op sCr  | 64.0 ± 21.1   | 47.9 ± 15    | 49.8 ± 10.9       | 27.1 ± 14.2 | 73.4 ± 18 |
| Mean ± SD          | 64.0          | 49.0         | 50.0              | 27.9    | 71.5 |
| Median             | 1.14 ± 0.5    | 1.39 ± 0.59  | 1.37              | 1.66    | 1.0 ± 0.36 |
| Last sCr           | 1.05          | 1.2          | 1.2               | 1.7     | 0.95 |
| Mean ± SD          | 71.6 ± 23.1   | 60.5 ± 23.5  | 62.1              | 42.2    | 77.9 ± 20.5 |
| Median             | 72.0          | 60           | 61.0              | 42.0    | 76.0 |

sCr- serum Creatinine; eGFR- estimated glomerular filtration rate. sCr unit is mg/dL. eGFR unit is ml/min. Significant P-values are shown in bold.
