A recombinant baculovirus encoding a single-chain murine major histocompatibility complex class I molecule in which the first three domains of H-2K\textsuperscript{d} are fused to $\beta_2$-microglobulin ($\beta_2$-m) via a 15-amino acid linker has been isolated and used to infect lepidopteran cells. A soluble, 391-amino acid single-chain H-2K\textsuperscript{d} (SC-K\textsuperscript{d}) molecule of 48 kDa was synthesized and glycosylated in insect cells and could be purified in the absence of detergents by affinity chromatography using the anti-H-2K\textsuperscript{d} monoclonal antibody SF1.1.1.1. We tested the ability of SC-K\textsuperscript{d} to bind antigenic peptides using a direct binding assay based on photoaffinity labeling. The photoreactive derivative was prepared from the H-2K\textsuperscript{d}-restricted Plasmodium berghei circumsporozoite protein (P.b. CS) peptide 253–260 (YIPSSEIK), a probe that we had previously shown to be unable to bind to the H-2K\textsuperscript{d} heavy chain in infected cells in the absence of co-expressed $\beta_2$-m. SC-K\textsuperscript{d} expressed in insect cells did not require additional mouse $\beta_2$-m to bind the photoprobe, indicating that the covalently attached $\beta_2$-m could substitute for the free molecule. Similarly, binding of the P.b. CS photoaffinity probe to the purified SC-K\textsuperscript{d} molecule was unaffected by the addition of exogenous $\beta_2$-m. This is in contrast to H-2K\textsuperscript{d}Q\textsubscript{lo}, a soluble H-2K\textsuperscript{d} molecule in which $\alpha$-m is noncovalently bound to the heavy chain. This is explained, on the one hand, by the intimate interactions of $\beta_2$-m not only with the $\alpha$-m domain but also with the $\alpha$ and $\alpha$2 domains, which is likely to be important for the conformation of the peptide binding site (Saper et al., 1991). On the other hand, stable assembly of the class I heterodimer depends on occupancy of the heavy chain peptide binding site (Townsend et al., 1989). Indeed, this hypothesis is supported by recent work with class I assembly-defective mutant cell lines (Townsend et al., 1989; Cerundolo et al., 1990; Townsend et al., 1990) and with purified human class I molecules (Silver et al., 1991), which has shown that suitable antigenic peptides promote class I molecule assembly. Furthermore, there is evidence that peptide epitopes induce a conformational change of the heavy chain, resulting in increased affinity for $\beta_2$-m (Elliott et al., 1991), and that free heavy chains present on the cell surface are functionally inactive (Rock et al., 1991a, 1991b).

Class I major histocompatibility complex (MHC)\textsuperscript{*} molecules are highly polymorphic 45-kDa integral membrane glycoproteins associated with the 12-kDa soluble $\beta_2$-microglobulin ($\beta_2$-m), and are involved in the presentation of endoge-

nously derived antigenic peptides to CD8-positive cytotoxic T lymphocytes (Townsend and Bodmer, 1989; Rothbard and Gefter, 1991). The general features of class I molecule biosynthesis have been known for some time both in vitro (Dobberstein et al., 1979) and in vivo (Krangel et al., 1979). N-Linked core glycosylation occurs during biosynthesis of MHC class I heavy chains in the endoplasmic reticulum (see Kornfeld and Kornfeld (1985) for review), and after $\beta_2$-m association (Sege et al., 1981), the heterodimer is transported along the secretory pathway to the cell surface (Owen et al., 1980). The mechanism by which endogenous antigenic peptides associate with class I molecules is still incompletely understood, but current evidence suggests that it takes place in the endoplasmic reticulum (Nutchern et al., 1989; Yewdell and Bennink, 1989; Kvist and Hammann, 1990).

The three-dimensional structure of HLA-A2 has revealed that the $\alpha_1$ and $\alpha_2$ domains of the heavy chain fold in a manner constituting an extended, groove-like peptide binding site (Bjorkman et al., 1987a, 1987b). Class I molecules on cell surfaces contain short peptides (8–10 amino acids) with distinct allele-specific binding motifs (Falk et al., 1991; Jardetzky et al., 1991). The binding of antigenic peptides to MHC class I molecules is closely interrelated to the binding of $\beta_2$-m to the heavy chain. This is explained, on the one hand, by the intimate interactions of $\beta_2$-m not only with the $\alpha_3$ domain but also with the $\alpha_1$ and $\alpha_2$ domains, which is likely to be important for the conformation of the peptide binding site (Saper et al., 1991). On the other hand, stable assembly of the class I heterodimer depends on occupancy of the heavy chain peptide binding site (Townsend et al., 1989). Indeed, this hypothesis is supported by recent work with class I assembly-defective mutant cell lines (Townsend et al., 1989; Cerundolo et al., 1990; Townsend et al., 1990) and with purified human class I molecules (Silver et al., 1991), which has shown that suitable antigenic peptides promote class I molecule assembly. Furthermore, there is evidence that peptide epitopes induce a conformational change of the heavy chain, resulting in increased affinity for $\beta_2$-m (Elliott et al., 1991), and that free heavy chains present on the cell surface are functionally inactive (Rock et al., 1991a, 1991b).

Clearly, further understanding of these interactions will depend on the availability of reconstituted systems using purified molecules. In this respect, the insect-baculovirus expression system has proved particularly useful in recent years for producing, in relatively large quantities, recombinant proteins that are authentically folded, proteolytically processed, post-translationally modified, and biologically active.
In this system, the foreign gene is cloned downstream of a strong very late promoter and introduced via homologous recombination back into the genome of Autographa californica nuclear polyhedrosis virus (AcNPV) (Miller, 1988; Luckow and Summers, 1989; Maeda, 1989). We have previously used this approach to produce biologically active mouse β2-m (Dargemont et al., 1989; Godeau et al., 1991) and a H-2Kd heavy chain which is able to associate with β2-m in an antigenic peptide-dependent manner and form a functional heterodimer able to bind peptides (Godeau et al., 1992). However, in doubly infected cells, the extent of association between the heavy and light chain is low and hence precludes isolation of larger amounts of assembled molecules. To circumvent this difficulty, we chose to express a fusion protein comprising the first three domains of H-2Kd heavy chain fused to mouse β2-microglobulin. We describe here some characteristics of this purified soluble protein and demonstrate that its interaction with antigenic peptides is identical to that observed with natural H-2Kd molecules.

MATERIALS AND METHODS

Cell Culture and Transfection—Suspension or monolayer cultures of the Sf9 cell line from Spodoptera frugiperda were maintained at 27°C in TC100 medium supplemented with 5% yeastolate (Difco) and containing 4% heat-inactivated fetal bovine serum, 50 μg/ml penicillin, and 50 μg/ml streptomycin. Cell densities were routinely kept between 2.5 × 10⁵ and 1.5 × 10⁹/ml by passing the cells in fresh medium. DNAs from recombinant plasmids (20 μg) and viral DNA (10 μg) were co-transfected by electroporation using a standard cuvette with a 0.4 cm gap containing 1 ml of Sf9 cell suspension (0.3–1.0 × 10⁶ cells/ml) in BNP (25 mM 2-[bis(2-hydroxyethyl)amino]ethanesulfonic acid, pH 6.95, 140 mM NaCl, 1.5 mM Na₂HPO₄, and 1 mM glucose) in the presence of 500 μg/ml hering sperm DNA and exposed to the exponential discharge of a 1030 pF capacitance charged under 900 V. Glycine-serine rich domains of H-2Kd heavy chain fused to the mouse Ps-rn' domain of H-2Kd will be described,* and the rabbit antiserum anti nuclear polyhedrosis virus (AcNPV) SC-H-2Kd Recombinant Baculovirus—All plasmids were constructed and purified according to standard recombinant DNA techniques (Sambrook et al., 1989) except that transformation of Escherichia coli hosts was performed by electroporation (Dover et al., 1988). Conditions for restriction endonuclease digestions were those suggested by the manufacturer. DNA fragments were isolated from agarose gels by electrodextraction. The transfer vector used in this study was the nonfusion pAcYM1 (Matsuura et al., 1989), kindly provided by Dr. D. Bishop, which was cleaved by digestion with BamHI restriction endonuclease and filled in with E. coli DNA polymerase large fragment. The structure of SC-Kd chimeric cDNA has already been described (Mottez et al., 1991). Briefly, the entire coding sequence comprises the four H-2Kd exons encoding H-2Kd signal sequence, α, α, and α domains fused to the mouse β2-m coding sequence lacking its signal sequence via a 45-base pair linker with the sequence: 5′GGG GGG ATC GGA TCC GGA GGC GGT GGA TCC GGT GGT GGC GGT TCG 3′. This DNA sequence, which encodes a 15-amino acid protein sequence predominantly composed of glycine and serine residues, was chosen for its expected flexibility and is represented in Fig. 1. To generate a recombinant baculovirus, SC-Kd chimeric cDNA was excised from pSC-Kd'15 (Mottez et al., 1991) by digestion with HindIII restriction endonuclease, filled in with E. coli DNA polymerase large fragment, and subsequently blunt-ended ligated into the filled in BamHI site of pAcYM1 transfer vector. Transformants were selected for proper orientation with respect to the polyhedrin gene transcriptional start site. Plasmid DNA was isolated and transfected together with viral DNA by electroporation, as already described (Chu et al., 1987; Godeau, 1990). Five to seven days after transfection, the viral progeny containing a mixture of wild type and recombinant viruses was subjected to a purification procedure based on limiting dilution in 96-well microtiter plates followed by selection on a SC-Kd probe. For seven days after transfection, the virus-containing, adhering cell monolayer was directly dissolved in 200 μl of 0.4 M NaOH and transferred to a nylon filter (GeneScreen Plus, Du Pont) via a dot-blot manifold (Reed and Mann, 1985). The filter was hybridized (Church and Gilbert, 1984) to a probe labeled (Feinberg and Vogelstein, 1983) H-2Kd probe, and the recombinant virus-containing medium from positive wells was further purified by a subsequent round of this dilution hybridization procedure leading to the isolation of AcNPV-SC-Kd. The chimeric mouse-murine β2-m, AcNPV-β2-m (Godeau et al., 1991), and H-2Kd heavy chain, AcNPV-Kd (Godeau et al., 1992), have already been described.

Purification of SC-Kd—Immunopurification matrices were prepared by using anti-H-2Kd monoclonal antibodies SF1.1.1.1 from ATCC and 34–1–2 (Ozato et al., 1980). Ten mg of pure IgG2a, mouse were covalently coupled to protein A-Sepharose (Pharmacia) via dimethylpipelimelidate following the procedure of Schneider et al. (1982). After saturating unreacted amino groups with ethanolamine and washing the column extensively, 1 liter of medium conditioned by AcNPV-SC-Kd-infected Sf9 cells was passed over the column during a 6-h period, after which the column was washed with 20 column volumes of phosphate-buffered saline. Bound material was eluted with 50 mM diethylylamine, pH 11.5, and the material was neutralized with 200 mM triethanolamine/HCl, pH 7.5, and concentrated. For affinity chromatography with concanavalin A, the cell-free conditioned medium was first ultracentrifuged (100,000 × g for 1 h), concentrated to one-tenth of the original volume, and dialyzed against 10 mM Tris, pH 7.5, 100 mM NaCl. The dialysate was passed through an immobilized concanavalin A column (IBF, France), eluted with α-methylmannoside, and analyzed by immunoblot using an anti-β2-m antiserum.

Biochemical Characterization of Purified SC-Kd—N-terminal sequence analysis of purified soluble SC-Kd insect cells was performed by automated Edman degradation after electrophoresis on SDS-PAGE and transfer to PVDF, as described (Matsudaira 1987), on an Applied Biosystems 470 gas-phase peptide sequanator. Phenylthiohydantoin amino acids were detected with an on-line Applied Biosystems 120 A analyzer. For internal peptide sequence determination, the purified protein was reduced and alkylated, transferred on PVDF membranes as described above and digested in 100 mM Tris- HCl, pH 8.5, with 1 μg of porcine trypsin (Sigma) in a 150 enzyme to substrate ratio for 4 h at 37°C. The digest was separated by HPLC on a C18 Vydac column (250 × 2.1 mm) using a 0–60% acetonitrile gradient in 0.1% trifluoroacetic acid. A well resolved peak was chosen for sequence determination.

Antibodies and Immunoblots—The class I H-2Kd-specific monoclonal antibodies used were 34–1–2 (IgG 2a) (anti-H-2Kd and H-2Dd) (Ozato et al., 1980) and SF1.1.1.1 (IgG 2a) from ATCC. All antibodies were purified from ascites fluid according to established procedures (Ey et al., 1976; Harlow and Lane, 1988). The rabbit serum raised against a fusion protein comprising the second half of the α2 and all of the α3 domain of H-2Kd will be described, and the rabbit antiserum anti mouse β2-m was from Dr. N. Tanigaki (Natori et al., 1976).

Immunoblots were performed by dissolving and analyzing protein samples on SDS-PAGE gels followed by electrophoresis on 12.5% polyacrylamide gels (Laemmli, 1970). Electrottransfer was performed using the semidy method (Kyhse-Andersen, 1984) with PVDF membranes (Immobilon Millipore) in 50 mM Tris-borate buffer, pH 8.5, after the gel had been equilibrated for 5 min in the same buffer containing 0.1% SDS. Membranes were blocked in TBS (50 mM Tris, pH 7.5, 200 mM NaCl, 0.05% Tween 20) containing 3% gelatin and incubated with a 1:500 dilution of the antiserum in TBS 1% gelatin, washed, and developed using alkaline phosphatase-labeled secondary antibody (Blake et al., 1984).

Peptide Synthesis—Peptides were synthesized using an Applied Biosystems model 430A peptide synthesizer and the standard t-butyloxycarbonyl strategy (Merrifield, 1986). The deprotected peptides were purified on a C18 reverse phase HPLC column, dissolved in phosphate-buffered saline, and stored frozen.

Photoaffinity Labeling with the 125I-SKDA-YIPSEAK(Biotin) Peptide Probe—The photoprobe was prepared by reacting freshly iodinated [125I]SKDA-ONSu with the biotinylated octapeptide from mouse malaria Plasmodium berghei circumsporozoite protein YIPSEAK(Biotin)I and purified by C18 reversed phase HPLC as previously described (Loescher et al., 1987, 1988). Ten mg of peptide labeled under anaerobic conditions were used for labeling whole cells, infected Sf9 cells were harvested after 48 h, washed in phosphate-buffered saline, resuspended (2 × 10⁵ cells/ml) in serum-free TC 100 medium in the presence of [125I]SKDA-YSPEAK(Biotin)I (1 × 10⁵ cpm) for 6 h at 27°C, and UV-irradiated at 4°C for 10 min (15 watt lamp with an emission maximum at 312 nm). After labeling, 2 F. Godeau and H. Ploegh, manuscript in preparation.
A Functional Soluble Single-chain H-2K^{d} in Insect Cells

the cells were washed twice in cold medium and once in phosphate-buffered saline, detergent solubilized in 0.7% Nonidet P-40, and immunoprecipitated using SF1.1.1. mAb. After 1 h the lysate was centrifuged (15,000 × g for 3 min), and the supernatant was filtered through disposable membrane filters (Millipore Nihon Kogyo, Yonezawa, Japan). Immunoprecipitation was performed on nitrocellulose membrane filters in a dot-blot manifold as described (Luescher, 1987).

For each immunoprecipitation, 30 µg of pure SF1.1.1. mAb was used. The immunoprecipitates were subjected to SDS-PAGE (10% acrylamide) under reducing conditions and the dried gels were exposed to XAR 5 (Kodak) films.

Photoaffinity labeling of purified SC-K^{d} protein was performed using a similar procedure. One µg of purified protein was incubated with [125I]ASA-YIPSEAK(biotin)I (1 × 10^{6} cpm) in 10 µl of phosphate-buffered saline. Aliquots were incubated in polypropylene tubes (500 ml Eppendorf, Hamburg, Germany) at 24 °C for 3 h. The tubes were UV-irradiated in the reflector of the described UV lamp for 3 min. The samples were diluted with 450 µl of phosphate-buffered saline containing 0.5% Nonidet P-40 and the labeled protein was photoprobe. The competitor was added 15 min before addition of the photoprobe. The competition experiments, 1 µg of purified protein was incubated with the photoprobe in the absence or presence of graded amounts of competitor peptides in 3-fold dilution steps up to 1000-fold molar excess with respect to the photoprobe. The competitor was added 15 min before addition of the photoprobe.

The K^{Q2} plasmid construct leading to the synthesis of a soluble chimeric heavy chain between the first two domains of H-2K^{d} and the third domain and the 3' sequences of the Q_{b}\,^{d} gene and its introduction into mouse L cells has been described (Luescher et al., 1992). Culture medium conditioned by clone NR37.15.2. was used to purify the K^{Q2}_{b} protein by immunofinity on an SF 1.1.1.1 column as described above.

RESULTS

Biochemical Characterization of SC-K^{d} Expressed in Baculovirus-infected Insect Cells—The SC-K^{d} construct, which comprises the signal sequence and the α1, α2, and α3 domains of the H-2K^{d} heavy chain cDNA fused to the coding sequence of murine β_{2}-m via a 15-amino acid flexible linker, is represented in Fig. 1. Assuming proper cleavage of its signal sequence, the mature chimeric polypeptide should be 391 amino acids long. Thus the molecular mass of the core polypeptide (without taking into account possible glycosylation) should be approximately 43 kDa. This chimeric construct has already been shown to lead to the synthesis of a soluble, glycosylated fusion protein after transfection in COS-1 cells (Mottez et al., 1991). To express this molecule in the higher amounts required for biochemical studies, we chose the recombinant baculovirus system. Thus, the use of the selection procedure described under "Materials and Methods" led to the isolation of a recombinant baculovirus containing the SC-K^{d} coding sequence under the transcriptional control of the polyhedrin promoter (AcNPV-SC-K^{d}). Preliminary experiments showed that a 48-kDa polypeptide (the expected apparent molecular mass for SC-K^{d} if one assumes that the two N-glycosylation sites are used) was present in the supernatant of metabolically labeled insect cells infected with this virus. This band could be immunoprecipitated by an anti-mouse β_{2}-m antisera as well as by the 34–1-2 mAb recognizing the native conformation of the H-2K^{d} heavy chain (Godeau et al., 1992) (results not shown). Taken together, these results indicate that the SC-K^{d} polypeptide is exported as a soluble protein in insect cells. In this fusion protein, the first three domains of the H-2K^{d} heavy chain associate with mouse β_{2}-m in a manner that mimics the native conformation of the heterodimer.

To purify this soluble class I fusion protein, immunofinity chromatography with an immobilized SF1.1.1.1. mAb column was carried out using crude cell-free conditioned medium from infected cells as starting material. Whereas no prominent Coomassie Blue stainable band could be detected in an SDS-PAGE analysis of the crude supernatant, the eluate from the affinity column showed a single major band of approximately 48 kDa (Fig. 2). This procedure routinely yielded approximately 500 µg of SC-K^{d} per liter of conditioned medium. Immunoblot analysis was carried out to further characterize the purified protein. In addition to reacting with the H-2K^{d}-specific rabbit antisera raised against a fusion protein containing half of the α2 and the entire α3 domain of H-2K^{d} (Fig. 3, panel A, lane a), this polypeptide also reacted with the anti-mouse β_{2}-m antibody (Fig. 3, panel A, lane b), indicating that the 48-kDa polypeptide contained both MHC Class I heavy and light chain sequences. We then analyzed the glycosylation of this molecule. Conditioned medium from serum-free cultures was thus passed over a concanavalin A column, and the α-methylmannoside eluate was analyzed by immunoblot using

---

**Fig. 1. Structure of the class I molecules used in this study.** Left, the membrane-associated class I H-2K^{d} heterodimer with noncovalently attached β_{2}-microglobulin. Middle, recombinant chimeric soluble molecule H-2K^{d}Q_{b}. The portion in boldface indicates the sequence originating from the Q_{b} class I gene. Although this molecule can associate with β_{2}-m, it has been represented without associated light chain. Right, recombinant chimeric soluble protein SC-H-2K^{d}. The sequence of the 15-amino acid flexible linker, inserted between amino acid 276 of the mature H-2K^{d} polypeptide and residue 1 of mature β_{2}-m, has been represented in the single letter code.

**Fig. 2. One-step purification of SC-K^{d} from the supernatant of SF9 cells using an immunofinity column.** One liter of serum-free culture medium conditioned for 72 h after infection by SF9 cells infected with AcNPV-SC-K^{d} was passed through an SF1.1.1.1. mAb immunofinity column, eluted at pH 11.5, and freeze-dried. Five µg of protein were loaded on an SDS-PAGE which was stained with Coomassie Blue. Lane a, eluate from the immunofinity column; lane b, molecular weight standards.
the anti-β2-m antiserum. As shown in Fig. 3, panel B, a prominent 48-kDa and β2-m immunoreactive band could be visualized in medium conditioned by AcNPV-SC-Kβ-infected cells which was absent from that of the wild type control, demonstrating that SC-Kβ contains mannose-rich carbohydrates.

To further confirm the identity of the purified protein, the 48-kDa polypeptide was sequenced following transfer onto PVDF membrane (thus further purifying the input protein). As shown in Table I, N-terminal sequencing yielded the sequence Gly-Pro-His, the expected N-terminal sequence of the mature H-2Kβ protein. This proves that the signal sequence of this polypeptide was cleaved in this expression system, as expected for a soluble protein recovered from a cell-free supernatant. Internal sequences were also obtained after tryptic digestion and separation of the digest by HPLC. One well separated peak was sequenced and shown to contain two distinct sequences in molar ratios differing by no more than a factor of 2. The first sequence, Tyr-Tyr-(Asp)-Gln, belongs to the H-2Kβ heavy chain and encompasses an N-glycosylation site. As expected for a glycosylated protein, the Asn residue is lacking in this sequence and replaced by a minute quantity of Asp. The second sequence, Ile-Pro-Lys, belongs to the mouse β2-m coding sequence, further indicating that the β2-m polypeptide was present in the SC-Kβ 48-kDa polypeptide. In view of the purity of the 48-kDa protein, no other peak was sequenced. Thus, among the three sequences obtained, all of them were derived from the expected sequences. Taken together, these results demonstrate that a soluble, 48-kDa, glycosylated SC-Kβ fusion protein with a correct N terminus is expressed efficiently in the baculovirus-insect cell system and can be isolated by a simple one-step procedure. In this polypeptide, the first three domains of H-2Kβ are physically linked to mouse β2-m and both sequences seem to fold to achieve a native conformation.

The Binding of IASA-YIPSAEK(biotin)I to SC-Kβ Is Not Affected by Soluble β2-m—We then determined whether the single-chain class I molecule retained the ability of the parental molecule to bind antigenic peptide ligands. We thus used the recently described H-2Kβ-specific photoprobe derived from the octapeptide 253-250 of the mouse malaria P. berghei circumsporozoite protein IASA-YIPSAEK(biotin)I. In as much as photo-cross-linking is several orders of magnitude faster than the interaction of peptides with class I molecules (De Graaf et al., 1974; Luescher et al., 1992), it directly reflects the binding of the peptide to class I molecules or any other cell component at the time of UV irradiation. We had previously shown that the binding of this photoprobe to the H-2Kβ produced in the baculovirus-insect cell system is dependent on the presence of β2-m (Godeau et al., 1992). We first examined the ability of the probe to label living insect cells infected with AcNPV-SC-Kβ. Thus, insect cells infected with various recombinant viruses were incubated with a 3 nM concentration of [125]IASA-YIPSAEK(biotin)I and UV-irradiated, and following detergent solubilization, the various Kβ constructs were immunoprecipitated and analyzed by SDS-PAGE and autoradiography. As shown in Fig. 4 (panel A), a strong labeling of the 48 kDa band was observed in extracts of cells synthesizing the SC-Kβ polypeptide (lane b). Similarly, the H-2Kβ heavy chain synthesized in the presence of β2-m, in S99 cells co-infected with AcNPV-Kβ and AcNPV-β2-m, strongly labeled as a 45 kDa band (lane a), but no labeling of the heavy chain could be detected in AcNPV-Kβ singly infected cells (lane c), nor was any band detectable in AcNPV-β2-m-infected cells (lane d) or wild type AcNPV-infected cells (lane e). These results demonstrate that the SC-Kβ produced in insect cells is functional in terms of binding the H-2Kβ-restricted photoprobe and that the β2-m molecule coupled to the heavy chain via the flexible 15-amino acid linker can replace free mouse β2-m, which is required for significant binding of the photoprobe (Godeau et al., 1992).

We then wished to examine the binding properties of the SC-Kβ protein by incubation of the purified protein with the photoprobe. As a control, we used the soluble class I molecule H-2KβQ, purified in the same manner, in which the heavy and light chains are produced as individual polypeptides and are therefore noncovalently associated. As shown in Fig. 4, panel B, this molecule was able to bind the photoprobe (lane c), but maximal labeling intensity required the addition of an excess of exogenous human β2-m (lane d). In contrast, purified SC-Kβ bound the photoprobe equally well in the absence or presence of an excess of human β2-m. Taken together, these results indicate that the SC-Kβ fusion protein can bind peptides in a manner similar to that of the parental class I heterodimer.

Inhibition of Photoreactive Peptide Binding to SC-Kβ by Unlabeled H-2Kβ-restricted Peptides—We next examined the specificity of the observed labeling of the SC-Kβ molecule, by competition in the presence of various concentrations of unlabeled peptides, some of which were bona fide Kβ-restricted peptides while others were peptide epitopes restricted by

![Table 1: Purified SC-Kβ N terminus and internal tryptic peptides](attachment:image)
either D\textsuperscript{0} or L\textsuperscript{d}. Photoaffinity labeling of the SC-K\textsuperscript{d} molecule by radiolabeled IASA-YIPSEAK(biotin)I was completely inhibited using a 10-fold molar excess of the parental octamer P. b. CS (YIPSAEKL) (Fig. 5, panel A). Similarly, a dose-dependent inhibition was observed when the 12-mer P.b. CS 249-260 was used as a competitor, but the molar excess needed for complete inhibition was higher, as expected for a peptide that is suboptimal with respect to the minimal consensus motif for K\textsuperscript{d}-restricted epitopes (Falk et al., 1991; Romero et al., 1991) (Fig. 5, panel B). The K\textsuperscript{d}-restricted P 198-peptide (Sibille et al., 1990) was also a good competitor, although not as potent as P. b. CS (YIPSAEKL) (Fig. 5, panel C). In contrast, the H-2D\textsuperscript{d}-restricted peptides Ad5 E1A 234–243 (Kast et al., 1989; Luescher et al., 1992) and NP 366–374 (Townsend et al., 1986) had no inhibitory activity (Fig. 5, panels D and E). Finally, P91A-12–24, a L\textsuperscript{d}-restricted peptide (Lurquin et al., 1989), did not show any inhibitory activity. Thus, the specificity of P. b. CS (YIPSAEKL) photoprobe binding to the single-chain K\textsuperscript{d} molecule correlated with the expected restriction pattern of the K\textsuperscript{d} molecule, indicating
that the observed labeling represents authentic binding to a functional peptide binding site.

**DISCUSSION**

In the insect cell-baculovirus system, recombinant proteins often retain their biological activity (Miller, 1988; Luckow and Summers, 1989; Maeda 1989) and are produced in considerable amounts, thus permitting their purification and detailed analysis. Indeed, our previous work using this system has provided evidence for a significant production of biologically active mouse $\beta_2$-m (Godeau et al., 1991) and of a functional H-2K$^d$ heavy chain which was able to associate with $\beta_2$-m in a peptide-dependent manner, so as to give rise to a functional heterodimer (Godeau et al., 1992). Since our ultimate goal is to study a reconstituted system with purified molecules, the lack of complete heterodimerization observed in doubly infected cells prompted us to seek a more efficient system to produce a soluble molecule. The only studies reporting the successful production of soluble class I molecules have used a truncated heavy chain associated with the substitution of the transmembrane domain of the Qb$^v$ molecule, leading to the production of a soluble class I molecule upon association with $\beta_2$-m (Margulies et al., 1986; Schneck et al., 1989). We have used another approach consisting of the creation of a fusion molecule of a truncated heavy chain linked to the light chain via a flexible 15-amino acid linker (Mottez et al., 1991). Although the transiently transfected COS-1 cells do not constitute an expression system suitable for preparative purposes, we have previously shown that the single-chain H-2K$^d$ molecule produced in COS-1 cells bears some resemblance to the natural class I molecule (Mottez et al., 1991), based on the presence of a conformational epitope recognized by the 34–42 mAb, which we have shown to be conformation-specific (Godeau et al., 1992). However, the peptide binding assay (Bouillot et al., 1989) used to initially assess the functionality of the fusion protein was subsequently reported to be of degenerate allele specificity (Chen et al., 1990; Frelinger et al., 1990).

We have expressed the truncated mouse class I major histocompatibility glycoprotein H-2K$^d$ in baculovirus-infected insect cells as a soluble, secreted fusion protein with mouse $\beta_2$-m. Here we provide direct evidence that SC-K$^d$ produces a soluble molecule which behaves as the native protein and should be particularly useful for peptide binding studies aimed at a biochemical and biophysical characterization of peptide-class I molecule complex formation.

**Acknowledgments**—We thank Dr. Tanigaki for the generous gift of antibodies, Dr. Bishop for the generous supply of vector, and Dr. G. Devauchelle for viruses and cell lines. We thank J. D’Aylayer for protein sequence determinations. We are also greatly indebted to Drs. G.P. Corradin, P. Romero, and J. Maryanski for the generous supply of peptides.
