Cytonuclear discordance in the Florida Everglades invasive Burmese python (*Python bivittatus*) population reveals possible hybridization with the Indian python (*P. molurus*)

Margaret E. Hunter, Nathan A. Johnson, Brian J. Smith, Michelle C. Davis, John S. S. Butterfield, Ray W. Snow, Kristen M. Hart

Abstract

The invasive Burmese python (*Python bivittatus*) has been reproducing in the Florida Everglades since the 1980s. These giant constrictor snakes have caused a precipitous decline in small mammal populations in southern Florida following escapes or releases from the commercial pet trade. To better understand the invasion pathway and genetic composition of the population, two mitochondrial (mtDNA) loci across 1,398 base pairs were sequenced on 426 snakes and 22 microsatellites were assessed on 389 snakes. Concatenated mtDNA sequences produced six haplotypes with an average nucleotide and haplotype diversity of $\pi = 0.002$ and $h = 0.097$, respectively. Samples collected in Florida from morphologically identified *P. bivittatus* snakes were similar to published cytochrome oxidase 1 and cytochrome b sequences from both *P. bivittatus* and *Python molurus* and were highly divergent (genetic distances of 5.4% and 4.3%, respectively). The average number of microsatellite alleles and expected heterozygosity were $N_A = 5.50$ and $H_E = 0.60$, respectively. Nuclear Bayesian assignment tests supported two genetically distinct groups and an admixed group, not geographically differentiated. The effective population size ($N_E = 315.1$) was lower than expected for a population this large, but reflected the low genetic diversity overall. The patterns of genetic diversity between mtDNA and microsatellites were disparate, indicating nuclear introgression of separate mtDNA lineages corresponding to cytonuclear discordance. The introgression likely occurred prior to the invasion, but genetic information on the native range and commercial trade is needed for verification. Our finding that the Florida python population is comprised of distinct lineages suggests greater standing variation for adaptation and the potential for broader areas of suitable habitat in the invaded range.

hybridization, invasive species, mitochondrial marker, nuclear microsatellite marker, phylogenetic population structure
1 | INTRODUCTION

Understanding the processes driving invasion dynamics of non-native species represents an important challenge for biologists and resource managers. Advancements in molecular tools and techniques have allowed for the delimitation of taxonomic units and genetic diversity, and identification of nonnative animals and plants in the absence of reliable morphological data (Bock et al., 2015; Darling, 2015; Serrao, Steinke, & Hanner, 2014). In many cases, only molecular information can elucidate the phylogeographic origin, transportation routes into nonnative ranges, and release history of nonnative species. Further, genetic tools can help identify source–sink population dynamics and movement pathways across invasion ranges for control and eradication efforts. Collectively, genetic characterization can inform management decisions and help to guide targeted removal efforts (Collins, Vazquez, & Sanders, 2002; Ficetola, Miaud, Pompanon, & Taberlet, 2008; Kolbe et al., 2007; McPhee & Turner, 2009; Stepien & Tumeo, 2006; Vidal, García-Berthou, Tedesco, & García-Marín, 2010).

Accurate and efficient identification and classification at the species level are necessary for invasive species management. For example, accurate species identification can indicate the required habitat types, diet (including prey species), intrinsic ecological constraints, and climatic suitability (Chown et al., 2015; Gotelli & Stanton-Geddes, 2015; Pfeiffer, Johnson, Randklev, Howells, & Williams, 2016; Rissler & Apodaca, 2007). Population expansion capabilities or limitations can be assessed through knowledge of the species life history, population growth rates, and susceptibility to diseases. Further, once the invasive species has been correctly identified, putative range expansions can be predicted using ecological niche models based on both the native and invasive species ranges (Ikeda et al., 2017; Mainali et al., 2015).

Understanding the potential for hybridization of invasive species is critical because diversity can be increased through crossing of divergent groups prior to release or during sustained releases over time of genetically divergent individuals. Hybridization events can lead to increased diversity, fitness, and fecundity in the invasive population (Kolbe et al., 2004, 2007; Vidal et al., 2010). Further, hybrid vigor and environmental selection can result in improved adaptation to the novel environment and increased areas of climatic suitability (Hahn & Rieseberg, 2017; Roman & Darling, 2007). Deleterious mutations can also accumulate through outbreeding depression via negative dominance effects (Oakley, Ågren, & Schemske, 2015).

In this study, we investigated putative origins, potential for hybridization with congeners, and population structure within the invasive Burmese python (*Python bivittatus*) population in the Greater Everglades Ecosystem (GEE) in Florida, USA. This giant constrictor snake has been reproducing in southern Florida since approximately the mid-1980s (Willson, Dorcas, & Snow, 2011). The cryptic nature of these snakes has limited detection and control efforts (Hunter et al., 2015; Reed et al., 2011), and the population has now expanded from Everglades National Park (ENP) into the eastern and western coasts of southern Florida and the Florida Keys (Dove, Snow, Rochford, & Mazzotti, 2011; Pittman et al., 2014; Snow, Brien, Cherikiss, Wilkins, & Mazzotti, 2007). Pythons are impacting the ecosystem through heavy predation on meso-mammals, including imperiled species, resulting in extensive declines of formerly common species (Dorcas et al., 2012; Mc Cleery et al., 2015; Reichert et al., 2017; Sovie, McCleery, Fletcher, & Hart, 2016).

*Python bivittatus* taxonomy and nomenclature have been uncertain in part due to the sympatric distribution with *P. molurus* in the native range and lack of a designated neotype (Jacobs, Auliya, & Böhme, 2009; Schleip & O’Shea, 2010). The species was first recognized by Kuhl (1820), but was then reclassified as a subspecies, *P. molurus bivittatus*, 100 years later. *Python molurus bivittatus* was differentiated as the other subspecies in the complex using subocular scales (Mc Diarmid, Campbell, & Touré, 1999). Most recently, *P. bivittatus* was again recognized as a distinct species with populations of *P. molurus* identified sympatrically (shared range) and possibly even syntopically (shared localities; Jacobs et al., 2009; Reynolds, Niemiller, & Revell, 2014; Schleip & O’Shea, 2010). The integrity of the two species and interbreeding avoidance in wild populations is thought to be maintained through resource partitioning of prey and microhabitat usage (O’Shea, 2007). Viable crosses, however, have been produced in captivity (Townson, 1980). Hybridization of the two species in the invasive range could affect climatic suitability and adaptation potential (as discussed previously) and also subsequent genetic analyses such as environmental DNA detection (Ryan et al., 2018; Wilcox et al., 2013). Here, we follow the most recent classification by Schleip and O’Shea (2010) and consider the Burmese python (*P. bivittatus*) and Indian python (*P. molurus*) as distinct species. To date, the GEE population has been morphologically identified as *Python bivittatus* throughout the invasive range.

A previous report of the invasive GEE population found one haplotype in cytochrome b (Cyt b) and two in the control region and used 10 cross-species microsatellites developed by Jordan, Goodman, and Donnellan (2002) to conclude that the ENP population was not genetically structured (Collins, Freeman, & Snow, 2008). The sequence data and several locus-specific and average genetic diversity values were not provided and therefore cannot be used for further comparison. Invasive Florida population-specific microsatellite markers for *P. bivittatus* were subsequently isolated (*N* = 18) and combined with six cross-species markers to identify 61% average expected heterozygosity (*H*<sub>e</sub>) and 2–6 alleles per locus (*N*<sub>A</sub>; 3.7 average *N*<sub>A</sub>; Hunter & Hart, 2013). In comparison, higher levels of genetic diversity (*N*<sub>A</sub> = 10.88) were identified for *P. bivittatus* in the native range using eight microsatellites (Duan et al., 2017).

Our goal was to more thoroughly characterize the *P. bivittatus* populations in Florida to inform research and management strategies. We compared two mitochondrial DNA (mtDNA) genes with population-specific nuclear microsatellite markers to investigate diversity, relatedness, effective population size, population structure, and introduction dynamics of *P. bivittatus* captured in Florida (Hunter & Hart, 2013). We further assessed phylogeographic structure and haplotype relationships and compared them with published
sequences in an effort to assess the genetic origin and species composition of introduced pythons in Florida.

2 | METHODS

2.1 | Sample collection and DNA extraction

The molecular analyses were conducted using tail tissue obtained from *P. bivittatus* samples collected January 2001 to September 2012. Samples originated in southern Florida from Everglades National Park, Collier County (including Big Cypress National Preserve), southeastern Miami-Dade County, and the Florida Keys (Figure 1). Burmese pythons were identified by the presence of a subocular scale just below the eye, which differentiates them from *P. molurus*, which possess supralabial scales that extend from the lip to the bottom of the eye (O’Shea, 2007). All tissues were stored at −20°C. DNA was extracted using QIAGEN DNeasy kits (Valencia, CA) or plate isolation protocols (Whitlock, 2000) was used to identify the genetic relationships and population parameters followed Hunter and Hart (2013), except for an annealing temperature of 57°C in MP4. All PCR products were analyzed on an ABI 3130xl (Applied Biosystems, Foster City, CA). Fragment data was scored using GeneMarker v. 1.97 (Soft Genetics, State College, PA). The majority of individual genotypes (*N* = 389) included all 22 loci, with a small percentage of samples missing ≤ seven loci.

2.2 | Microsatellite analysis

2.2.1 | Microsatellite DNA analysis

To address fine-scale genetic diversity and population structure in the invasive population, 18 population-specific microsatellites were developed through next-generation sequencing and incorporated with six cross-species loci (Jordan et al., 2002) into eight multiplexes to reduce laboratory effort (Hunter & Hart, 2013). Of these markers, two loci (MS16 and MS22) did not produce consistent scores and were excluded here. To optimize previously published annealing multiplex (MP) temperatures, Pmb-U21 was reassigned to MP1 and MS09 was reassigned to MP9. Annealing temperatures and PCR parameters followed Hunter and Hart (2013), except for an annealing temperature of 57°C in MP4. All PCR products were analyzed on an ABI 3130xl (Applied Biosystems, Foster City, CA). Fragment data were scored using GeneMarker v. 1.97 (Soft Genetics, State College, PA). The majority of individual genotypes (*N* = 389) included all 22 loci, with a small percentage of samples missing ≤ seven loci.

2.2.2 | Microsatellite statistical analysis

*MicrO-CHECKER* (Van Oosterhout, Hutchinson, Wills, & Shipley, 2004) was used to identify loci with evidence of null alleles. *GENECAP* (Wilberg & Dreher, 2004) calculated the probability of identity (*P*<sub>ID</sub>), which is the probability that two individuals drawn at random from a population will have the same genotype at the assessed loci (Paetkau & Strobeck, 1994) and sibling probability of identity (*P*<sub>IDSB</sub>), a related, more conservative statistic for calculating *P*<sub>ID</sub> among siblings (Evett & Weir, 1998). The program additionally searched for duplicate genotypes.

The program *STRUCTURE* 2.3.4 (Pritchard, Stephens, & Donnelly, 2000) was used to identify the genetic relationships and population structure of the southern Florida population. *STRUCTURE*, a model-based clustering algorithm, infers population structure by probabilistically assigning individuals, without a priori geographic or ancestral knowledge, to a specific number (K) of clusters (presumably populations). In determining the number of clusters, the algorithm attempts to minimize deviations from Hardy–Weinberg equilibrium (HWE).

Simulations were conducted using the correlated allele frequency model and admixture model, which assumes that individuals could have some proportion of membership (q) from each of K clusters. Multiple Markov chains can delineate differences within populations; therefore, 20 parallel chains were analyzed for K = 1–11, with a run length of 200,000 Markov chain Monte Carlo repetitions, following a burn-in period of 50,000 iterations. The most probable number of groups, K, was assessed using the mean log likelihood (Ln P(D)) and by calculating ΔK, an ad hoc quantity related to the change in posterior probabilities between runs of different K values (Evanno, Regnaut, & Goudet, 2005), in *STRUCTURE HARVESTER* (Figure 2; Cristescu, Sherwin, Handasyde, Cahill, & Cooper, 2010). Individual assignment success was recorded as the highest likelihood of assignment (q), and the percentage of individuals in a cluster with q ≥ 0.90 was calculated. *GENECLEAN* was used to detect first-generation migrants born in a population other than the one in which they were sampled without a priori population categorization (Piry et al., 2004). We used the Paetkau, Calvert, Stirling, and Strobeck’s (1995) simulation algorithm and *I*<sub>s</sub> to assess the likelihood of finding individuals in the population in which they were sampled, which is most appropriate when all potential source populations have not been sampled. Migrant detection was assessed using the critical value (0.01; Paetkau, Slade, Burden, & Estoup, 2004).

The following statistical tests were conducted for the population as a whole and to assess the accuracy of the *STRUCTURE*-identified groups. The genetic diversity was estimated by the *H*<sub>e</sub> and observed heterozygosity (*H*<sub>o</sub>), information index (*I*), *N*<sub>e</sub>, average effective number of alleles (*E*<sub>a</sub>), and private alleles (*P*<sub>a</sub>) using GenAlEx 6.501 (Table 1, Supporting Information Table S1; Peakall & Smouse, 2006). Departures from the expected genotypic frequencies in HWE were tested using the Markov chain method, and linkage disequilibrium expectations were tested using the randomization method of Raymond and Rousset (1995) for all pairs of loci within collections to test for the presence of admixture in Genepop 4.0 (dememorization, 1,000; batches, 100; iterations per batch, 1,000; Raymond & Rousset, 1995). Sequential Bonferroni adjustments (Rice, 1989) were used to determine significance for these tests.

To assess genetic differentiation of the clusters identified by *STRUCTURE*, *GenAlEx* 6.501 was used to calculate *F*<sub>ST</sub> and *R*<sub>ST</sub> via analysis of molecular variance (AMOVA) within and among clusters and individuals with 9,999 permutations. The statistical significance of the correlation between genetic and geographic distance matrices, or isolation by distance, was assessed with a Mantel randomization test performed with *GenAlEx* 6.5 with 999 permutations comparing pairwise genetic distance (in meters; Paetkau & Strobeck, 1994). The genetic groupings were assessed by the LDeN software (Waples & Do, 2008) to estimate effective population sizes (*N*<sub>E</sub>) using the linkage
disequilibrium (LD) method at the three lowest allele frequency levels (0.01, 0.02, and 0.05), with 95% confidence intervals (CI) following the bias-corrected method of Waples (2006). The single point estimate method removes the downward bias associated with the true $N_e$ being greater than the sample size used to estimate it (Waples, 2006).

We used **Bottleneck** 1.2.02 to evaluate heterozygote excess of populations under the sign test, one-tailed Wilcoxon’s signed-rank test for mutation-drift equilibrium, and the allele frequency distribution test (Table 2; Piry, Luikart, & Cornuet, 1999). The Garza–Williamson index and modified index were calculated in Arlequin 3.5 (Excoffier & Lischer, 2010). The Garza–Williamson index is the mean ratio of the number of alleles at a given locus to the range in allele size ($M$; Garza & Williamson, 2001). It is assumed that during a bottleneck event, the number of alleles decreases faster than the allelic range. A bottleneck is indicated with a critical value of $M < 0.68$, and no reduction of effective population size is indicated at $M > 0.80$. 

**FIGURE 1** Map indicating python sample locations in southern Florida, USA. The nuclear Bayesian clustering assignments are shown in color. The samples yielding only mitochondrial DNA (mtDNA) sequences are in gray. Overlapping sample points have been offset to increase resolution.
GenAlEx 6.501 was used to calculate $F_{IS}$, which is close to zero when the population is undergoing random mating. Mean relatedness values ($r_{xy}$) were computed for all pairwise relationships via ML-RELATE (Kalinowski, Wagner, & Taper, 2006). Relatedness and individual inbreeding coefficients ($F_r$) were estimated for all pairwise relationships via COANCESTRY (Wang, 2011). From mean relatedness values, latent coancestry ($\Theta_{xy}$) was calculated following Lynch and Ritland (1999), where $r_{xy} = 2\Theta_{xy}$. To better understand the capacity to increase genetic diversity in the population, relatedness was also estimated specifically for eight collected hatchlings from a

Note: Sequences are grouped by *Structure* clusters obtained through nuclear microsatellite genotypes \((N = 293)\) and sequences \((N = 399)\). Note that 106 samples did not contain data for both marker types.
alignment (Sequence ID: ISDB081-13.COI-5P). The second sequence (ISDB016-11.COI-5P) was from a snake housed in a zoo in the same state and differed by four base pairs (bps) from ISDB081-13. *Python regius* (Dong & Kumazawa, 2005) was included as the basal member of the python genus (Reynolds et al., 2014).

Pairwise genetic distances were calculated using Tajima-Nei between the invasive population samples and *P. molurus* sequences published in GenBank and the Barcode of Life Data (BOLD) system (www.barcodinglife.org; Ratnasingham & Hebert, 2007; Tajima & Nei, 1984) using MEGA7 (Kumar, Stecher, & Tamura, 2016; Supporting Information Tables S4 and S5). Polymorphic sites and the corresponding diagnostic sites were determined by the alignment of published haplotypes and haplotypes identified in this study (Supporting Information Tables S6 and S7). Genetic differentiation was tested with an analysis of molecular variance (AMOVA) in Arlequin 3.5, using models of DNA sequence evolution selected by the Akaike information criterion (AIC) and Bayesian information criterion (BIC) in MEGA7 (Kumar, Stecher, & Tamura, 2016; Excoffier & Lischer, 2010; Guindon & Gascuel, 2003). The T92 model (Tamura, 1992) was selected for CO1 sequences. The TN93 model (Tamura & Nei, 1993) was selected for Cyt b and concatenated (CO1 [N = 598] and Cyt b [N = 799]) analyses.

We created haplotype networks using PopART (Leigh & Bryant, 2015) to assess the geographic distribution of mtDNA diversity and compare relationships between our samples and those previously published (Figure 3). Default minimum spanning network settings were used to generate a haplotype network with pie charts representative of the proportion of samples grouped by Structure clusters. The number of base pair discrepancies between haplotypes is provided in parenthesis.

3 | RESULTS

To summarize the results, 11 mtDNA haplotypes (GenBank Accession Number: MH357840-50) were identified with high haplotype diversity in the invasive python samples corresponding to both *P. bivittatus* and *P. molurus*. Nuclear microsatellite markers detected lower diversity and NE as compared to native range samples, likely related to founding and bottleneck effects. Bayesian clustering analyses identified two distinct nuclear groups and an admixed group with no correlation with geographic distribution. The *P. molurus* haplotypes were more predominantly classified in cluster 2.

3.1 | Microsatellite DNA analysis

Only the MS13 locus in cluster 1 indicated the evidence of null alleles due to homozygote excess (>0.05), but there was no evidence of stuttering, large allele dropout, or linkage disequilibrium. The loci produced an unbiased $P(ID)$ estimate of 5.63 E−15 and a $P(ID)_{sib}$ estimate of 2.99 E−07, indicating that unique individuals can be confidently identified across the region. The Bayesian Structure Ln P(D) estimates indicated similar values and generally plateaued at K = 4 clusters, while the Structure harvester analysis according to

Note. An asterisk (*) denotes significance at p < 0.05.

TABLE 5 | References and GenBank accession number or BOLD sequence ID (www.boldsystems.org) for the published haplotypes used in the study

Note. The prefix indicates the most similar species (*P. bivittatus*, Pb; *P. molurus*, Pm), and the gene is identified as either cytochrome b (Ctb) or cytochrome oxidase 1 (CO1). Direct submission sequences deposited in the databases are not associated with a publication. Country of origin is indicated for the sample or authors.
Evanno et al. (2005) strongly supported $K = 2$ clusters (Figure 2). The $K = 4$ and next highest $\Delta K$ ($K = 6$) were also investigated; however, the majority of the genotypes were “roughly symmetrically” assigned across the four or six populations, respectively, indicating that these values of $K$ are not identifying real population structure (Supporting Information Figure S1; Pritchard et al., 2000). Therefore, as recommended, $K = 2$ was selected and groups were assigned as follows: cluster 1 ($N = 292$), cluster 2 ($N = 42$), and a third, admixed group ($N = 55$), containing $q \leq 90\%$ assignment to the two clusters (Figure 2; Evanno et al., 2005; Pritchard et al., 2000).

Across the 389 samples, Hardy-Weinberg disequilibrium was found for $Pmb-N14$ and $Pmb-Z26$ ($p \leq 0.002$). After the sequential Bonferroni adjustments, linkage disequilibrium was found for 39 of 231 (16.9%) comparisons, likely due to population substructure tested below. Separate analyses of the three groups identified in Structure resulted in HWE for all loci and linkage equilibrium for cluster 1 and admixed. However, linkage disequilibrium was found in cluster 2 for two pairs of loci ($Pmb-S19$ and $Pmb-R18$, $Pmb-N14$ & $Pmb-K11$). This deviation may be due to inbreeding or cryptic subpopulation structure (i.e., Wahlund effect). GeneClass detected 16 samples with a probability <0.01. These samples were all members of cluster 2 defined by Structure.

$F_{ST}$ values among the three Structure-defined clusters were low, but significant ($p \leq 0.017$): cluster 1 versus 2 (0.029), cluster 1 versus admixed (0.004), and cluster 2 versus admixed (0.012). $R_{ST}$ values were not significant, likely owing to the minimal time for mutations to occur. Low levels of nuclear diversity were found for all samples as assessed together and grouped by clusters (Table 1). The AMOVA identified moderate variation both among the three Structure clusters and within individuals (19.12% and 1.49%, respectively). In cluster 2, 19 private alleles were found in 33 samples, while the admixed group
Mitochondrial DNA haplotypes partitioned by Structure clusters

The Structure cluster 1 contained only the Pb-FL-H01 haplotype in all but one sample, while cluster 2 and the admixed groups contained a mixture of haplotypes (Table 3). The majority of the haplotypes were each assigned to a single cluster (Table 3). Interestingly, although not selected as the correct grouping, many of the samples with *P. molurus* haplotypes were assigned to a single cluster in the K = 4 plot (green; Supporting Information Figure S1). Diagnostic sites differentiating the two *Python* species were identified for the two loci: Cyt b (*N* = 27) and CO1 (*N* = 24; Supporting Information Tables S6 and S7). The highest differences between concatenated sequences, as measured by Φs, and exact test values, were between the cluster 1 and 2 Structure groups (*p* < 0.05; Table 4). The mtDNA AMOVA values within and among the three Structure groups resulted in relatively high variation (69.96% and 30.04%, respectively). The AMOVA identified variation levels of 48.60% and 51.40% within and among clusters 1 and 2, respectively.

Comparison with published sequences

The dominant Cyt b haplotype that we found in the invasive range matched all but one nucleotide to one of the published *P. bivittatus* mitochondrial genome sequences (Pb-Ctb-A; Supporting Information Table S4; Liu et al., 2013). The next highest frequency haplotype differed by ≥4.13% from Liu et al. (2013), but was only ≤0.76% different from the published *P. molurus* sequences (Dubey et al., 2012; Slowinski & Lawson, 2002). A similar pattern was found for the CO1 haplotypes with a dominant haplotype most closely resembling *P. bivittatus*. The second most dominant haplotype matched *P. molurus* or differed by 1.38% (Supporting Information Table S5). No sublocus differentiation was found in the available photographs of the snakes containing *P. molurus* haplotypes. There was some disparity between the published sequences and associated species labels, which may relate to the lack of consensus in the nomenclature.

Discussion

The invasive Burmese python population in Florida appears to be derived from multiple genetic sources with strongly divergent mitotypes corresponding to species-level differentiation. The Cyt b genetic distance (4.3%) was larger than the distance found in the most recent taxonomic assessment that separated *P. bivittatus* and *P. molurus* into species (2.9%; Reynolds et al., 2014). The CO1 genetic distance (5.4%) was also greater than the distances for the two species published in BOLD (4.1%). In the literature, CO1 nucleotide diversity values lower than 4.1% have been used as a minimum threshold to distinguish interspecific variation from intraspecific divergence (Gomes, Pessali, Sales, Pompeu, & Carvalho, 2015; Ratnasingham & Hebert, 2013). In contrast to the strong
mitochondrial differentiation signals, minimal divergence was detected between the three Bayesian clusters at nuclear microsatellites ($F_{ST} \leq 0.029$).

In vertebrates, cytonuclear discordance is indicated by conflicting signals between mtDNA and nuclear genetic diversity. The nonrecombining mitochondrial genome sequence remains as a distinct cytotype in an admixed clade until, over time, only either the dominant (parent) or introgressed cytotype is retained (see Seehausen, 2004). On the contrary, admixed nuclear genotypes will continue to recombine with the dominant alleles until introgressed. During the intermediate phase, nuclear genome hybrids and both cytotypes can be detected. Cytonuclear discordance can be caused by hybridization, incomplete lineage sorting, direct balancing selection, indirect selection, or pseudogenes (Grobler, Jones, Johnson, Neves, & Hallerman, 2011; Thielch, Knell, Mohammadyari, Petrusek, & Schwenk, 2017). In our data, incomplete lineage sorting is unlikely due to the high sequence divergence among the samples and rapid progression of lineage sorting in mitochondrial loci (Funk & Omland, 2003). Similarly, no evidence for indirect selection or pseudogenes causing cytonuclear discordance was observed here, given the haplotype sequences and divergence levels. It is possible that we detected direct balancing selection of rare ancestral mitochondrial lineages that favor specific environmental conditions; however, the role that mtDNA plays in natural selection is not fully understood (Funk & Omland, 2003). Most likely, the cytonuclear divergence we detected is the result of hybridization between snakes contributing mitochondrial genome sequences from both species.

Past hybridization of *P. molurus* and *P. bivittatus* may have led to the identified cytonuclear discordance in the invasive population. The nuclear $F_{ST}$ values $\leq 0.029$ suggest significant introgression of the nuclear genomes and a population-level, as opposed to a species-level, divergence. However, residual *P. molurus* nuclear genomic material may be contributing to the cluster 2 and admixed genotypes. For instance, in cluster 2, 16 first-generation migrants were detected, and 19 private alleles were found in 79% of the individuals (with 10 individuals identified in both analyses). In natural systems, the sigmoid shape of the STRUCTURE plot (Figure 2) can be interpreted as hybridization followed by selection against the hybrid alleles or segregating variation. However, as this population was likely released from the pet trade, the admixed group may indicate separate introductions of two relatively similar gene pools that are now interbreeding over a few generations.

The taxonomic uncertainty regarding species boundaries in the genus *Python* complicates our understanding of the precise mechanism responsible for the cytonuclear discordance. Introggression of the diverse lineages could occur through interbreeding (a) in the native range through sympatric associations or secondary contact (Seehausen, 2004), (b) during secondary contact in captivity, or (c) after release into the invasive range, possibly in part due to unidirectional hybridization or unbalanced sex ratios in hybrid generations (Firmat, Alibert, Losseau, Baroller, & Schliewen, 2013). The support for scenario 3 is limited, given the low diversification in the nuclear genome suggestive of admixture over numerous generations. More extensive native range phylogeographic sampling of mtDNA and nuclear DNA loci is necessary to confirm whether the cytonuclear discordance observed in Florida is present in native populations or occurred after capture. Limited introgression of *P. molurus* followed by backcrossing to *P. bivittatus* may have occurred in the large, widely distributed commercial trade populations. Alternatively, intraspecific genetic divergence in the *P. bivittatus* native range may have contributed to the three nuclear groups found in China ($F_{ST} = 0.11$ overall), although assessment of mitochondrial DNA is needed to determine whether divergent mitotypes are also present (Duan et al., 2017).

Field observations in the native range indicate that the two species utilize distinct habitats with some overlapping ranges. *Python bivittatus* prefers riverine forests and flooded grasslands, while *P. molurus* occupies dry, sandy, and woodland areas (Schleip & O’Shea, 2010). Hybridization of the two species could allow for improved acclimatization and adaptability to abiotic stressors or climate change and result in broader or more rapid distributions of the invasive population (Hoffmann & Sgrò, 2011; Mazzotti et al., 2011; Rodda, Jarnevich, & Reed, 2009). Currently, pythons occupy both wetlands in Everglades National Park and drier, sandy pinelands with interspersed wetlands in western Collier County. However, evidence of a panmictic population was found with no temporal or phylogeographic pattern across the sampled range. This is not surprising, given that invasive pythons are known to disperse long distances (Hart et al., 2015).

A bottleneck and/or founding event was indicated 0.2–4 $N_e$ generations ago with a $\geq$90% reduction in population size (Williamson-Natesan, 2005). Given that Burmese pythons require two to five years to reach sexual maturity (Willson, Snow, Reed, & Dorcas, 2014), the population would have undergone approximately four to 10 generations after being founded in the mid-1980s (Willson et al., 2011). The detection of a bottleneck of less than four generations ago may indicate a secondary bottleneck due to novel environmental conditions such as cold-induced mortality (Mazzotti et al., 2011). Alternatively, a lag in the generation times or in the population growth rates may have occurred shortly after the population’s founding, possibly due to low propague pressure (Fujisaki et al., 2010). Reproduction was not documented until the first wild hatchlings were found in the mid-1990s (Meshaka, Loftus, & Steiner, 2000), although detection of pythons has remained low until recently (Hunter et al., 2015; Reed et al., 2011). Parthenogenesis has also been identified in the species, which may allow for population expansion even at low densities and would contribute to reduced genetic diversity (Groot, Bruins, & Breeuwer, 2003).

In comparison with our findings, on average, native range Burmese pythons had nearly twice the number of alleles and higher average heterozygosities, with the exception of the Yunnan population, which had similar allelic values ($N_A = 5$; Duan et al., 2017). In the invasive population, effective population sizes were relatively low, supporting the hypothesis that the population was established by a small number of founders and/or closely related individuals (Willson et al., 2011). Monitoring of the effective population size could help to identify changes in the census size as genetic mutations occur and accumulate, especially in order to assess effective control efforts (Hauser, Adcock, Smith, Bernal Ramázé, & Carvalho, 2002; Hui & Burt, 2015). More accurate effective population size estimates with
lower variance can be calculated with genetic data collected over multiple generations (Hui & Burt, 2015).

While the genetic diversity in the invasive Burmese python population is lower than that found in the native range, it is likely to increase in the large, rapidly growing invasive population, especially if additional animals are released. Multiple paternity was identified in the invasive population which could also contribute to accelerated increases in diversity. Of note, the genetic confirmation of multiple breeding events by different sires lends support to the Judas control technique in which radio-tagged snakes are used to reveal the location of conspecifics during breeding (Smith et al., 2016). Over time, as the population expands, some genotypes may become isolated or fixed, adapting to certain habitats and creating more population structure.

Recently, eDNA has become an important tool to estimate occurrence and detection probabilities and track the invasion front of the Burmese python populations (Hunter et al., 2015; Piaggio et al., 2013). Highly divergent mtDNA sequences could lead to mispriming of eDNA primers or probes, resulting in false negatives, along with potentially lower detection and occurrence estimates (Wilcox, Carin, McKelvey, Young, & Schwartz, 2015; Wilcox et al., 2013). Deep sampling is necessary to detect intraspecific variation found at low frequencies in the population.

The limited number of well-documented, high-quality published sequences hinders our ability to investigate P. bivittatus and P. molurus species boundaries. Morphological voucher specimens and broader phylogeographic sampling throughout the native range, including sympatric areas, could improve taxonomic uncertainty. Further, genomic-level assessment and transcriptomic studies could address fine-scale population structure and the Burmese python’s adaptation to the novel environment (Castoe et al., 2011; Rodda et al., 2009; Wall et al., 2011). Findings from these endeavors could facilitate management in a variety of ways, including the development of effective monitoring tools (e.g., eDNA assays) and more accurate range expansion predictions.

ACKNOWLEDGMENTS

We would like to thank Gaia Meigs-Friend and Theresa Floyd (USGS) for laboratory support, Michael Cherkiss (USGS) for field assistance, Tylan Dean (National Park Service, Everglades National Park), Paul Andreadis (Denison University) and Ian Bartoszek (Conservancy of SW Florida) for sample coordination, Jason Ferrante and Breanna Caton (USGS) for assistance with data analysis, and Michelle Giles. The protocol was approved by the US Geological Survey, Wetland and Aquatic Research Center Institutional Animal Care and Use Committee (IACUC; Permit Number: USGS/SESC 2013–04). Additionally, all samples were collected under the National Park Service (NPS; Everglades) Permit Number: EVER-2007-SCI-001 and EVER-2009-SCI-001.
