Abstract

When facing a traumatic event, some people may experience positive changes, defined as posttraumatic growth (PTG). A collective experience of trauma can help people reflecting on their traumatic experiences, as it would be the case for the COVID-19 pandemic. Understanding the possible positive consequences of the pandemic on the individual level is crucial for the development of preventive and supportive psychosocial interventions for the general population.

The present paper aims to: 1) evaluate the levels of PTG in a sample of the general population; 2) to identify predictors of each dimension of post-traumatic growth.

The majority of the sample (67%, N=13,889) did not report any significant improvement in any domain of PTG. Participants reported the highest levels of growth in the dimension of “appreciation of life” (2.3±1.4), while the lowest level was found in the “spiritual change” (1.2±1.2). Female participants reported a slightly higher level of PTG in the dimensions of personal strength (p<.002) and appreciation for life (p<.007) compared to male participants, while no significant association was found with age.

At the multivariate regression models, weighted for the propensity score, only the initial week of lockdown (between April 9 – April 15) had a negative impact on the dimension of “relating to others” of the PTG (B= -.107, 95% CI= -.181 to -.032, p<.005), while over time no other effects were found. However, the duration of exposure to lockdown measures did not influence the other dimensions of PTG.

The assessment of the levels of PTG in the general population during the initial phase of the national health emergency is of great importance for the development of ad hoc supportive and preventive psychosocial interventions. From a public health perspective, the identification of protective factors is crucial for developing ad-hoc tailored interventions and for preventing the development of full-blown mental disorders in large scale.

Key-words: pandemic, trauma, post-traumatic growth, coping strategies, resilience, COVID-19, mental Health
Introduction

The COVID-19 pandemic has had a profound negative impact on the mental health of the general population [1-3]. The pandemic can be considered as a new type of traumatic stressor, being an unexpected event, affecting the whole population worldwide and causing a severe disruption of daily routine life [4-6]. Recent research suggests that traumatic stress reactions, including intrusive re-experiencing and heightened arousal, are frequent during the pandemic [7] and may be due to its direct threats to important life resources of the general population, such as safety, health, income [8], work, housing, and social support [9-10]. Furthermore, the traumatic stress reactions to the COVID-19 pandemic may be worsened by the indirect exposure to the pandemic, e.g., via mass-media coverage and the phenomenon of infodemic [11,12]; by the psychosocial consequences of the pandemic, in terms of unemployment, isolation [13], non-sudden illness/death [14-16]; and by the lack of clear and reliable therapeutic guidelines for the management of the COVID-19 infection [17].

The negative consequences of the pandemic on the mental health may be very different in different target populations, such as healthcare professionals, people infected by the COVID-19, people living with disabilities or affected by chronic physical and mental health disorders [18] or special population, such as pregnant women [19-24], elderly [25,26] or young people [27-30]. In particular, the psychiatric and psychological consequences of the pandemic on the general population mainly include high levels of distress [31,32] and of post-traumatic reactions [33-35], social isolation with suicidal ideation [36-39], depressive and anxiety symptoms and sleep disorders [40-44]. A high prevalence of mental exhaustion, burn-out syndrome and insomnia has been found in healthcare workers [45-47]. In disabled people and in those with pre-existing mental health problems, an increased risk of treatment interruption of long-term treatments has been found, associated with relapses or symptoms worsening, as well as with a higher risk of being infected by the COVID-19 [48-53]. Specific risk factors identified for the development of these mental health disturbances include female gender, having previous psychiatric or physical disorders, loneliness, time spent on the Internet, and unemployment [54-55]. Although these different populations are exposed to the same traumatic event (i.e., the pandemic), its perception is highly variable, because it is mediated by individual psychological and social factors, such as coping strategies and resilience styles [56-60].
When facing a traumatic event, some people may also experience positive changes, the so-called posttraumatic growth (PTG) [61,62]. The PTG is a substantive, positive change in a person’s self-perceptions, relationships with others, and/or their personal philosophy of life, resulting after a traumatic experience [63,64]. PTG consists of five dimensions [65]: 1) changes in how people relate with others (i.e., an increased willing to express emotions or even accepting more likely help from others); 2) recognition of new possibilities (i.e., seen as an increased attitude to take new paths in life and redefine priorities); 3) a sense of greater personal strength (i.e., improved sense of self-efficacy, strength, and self-confidence); 4) changes toward spirituality (i.e., religious beliefs, spiritual matters, and existential/philosophical questions); and 5) greater appreciation of life (i.e., considering meaningful and worth in life’s little things).

Some studies [66-70] highlighted how a collective experience of trauma can help people reflecting on their traumatic experiences, as it would be the case for the COVID-19 pandemic [71]. Understanding the possible positive consequences of the pandemic on the individual level is crucial for the development of preventive and supportive psychosocial interventions for the general population [72-76]. Furthermore, the socio-demographic and clinical factors facilitating the positive adaptation to trauma may be worth to identify.

During the initial phase of the pandemic, Italy has been among the most severely hit countries, with high rates of COVID-related morbidity and mortality, high occupancy rate in intensive care units and extreme burden on the national health systems. Therefore, the Italian government issued severe public health measures, with lockdown and quarantine in order to limit the spread of the disease. The COvid Mental hEalth Trial (COMET) study is a multicentric, collaborative, not-funded trial carried out during the initial phase of the COVID-19 pandemic, targeting the Italian general population during the first wave of the lockdown [54,77].

Based on the COMET study, the present paper aims to: 1) evaluate the levels of PTG in a sample of the general population; 2) to identify predictors of each dimension of post-traumatic growth.

Materials and Methods

The present paper is based on data collected in the COvid Mental hEalth Trial (COMET) [54,77].
The COMET study has been coordinated by the University of Campania “Luigi Vanvitelli” (Naples), includes other Italian university sites (Università Politecnica delle Marche (Ancona), University of Ferrara, University of Milan Bicocca, University of Milan “Statale”, University of Perugia, University of Pisa, Sapienza University of Rome, “Catholic” University of Rome, University of Trieste) and the Center for Behavioral Sciences and Mental Health of the National Institute of Health in Rome. The COMET trial has been designed as cross-sectional study, adopting a snowball sampling procedure [77].

The main outcome measure considered in the present study is represented by the levels of Post Traumatic Growth, which have been evaluated by using the short form of the PTGI [78]. The PTGI consists of 10 items, rated on a 6-point Likert scale (i.e., 0 = “I did not experience this change as a result of my crisis”; 5 = “I experienced this change to a very great degree as a result of my crisis”). Items are grouped in following five dimensions: 1) relating to others; 2) new possibilities; 3) personal strengths; 4) spiritual change; 5) appreciation of life. It is calculated a total score, so that higher scores indicate higher levels of post-traumatic growth. Responses on the items were averaged to form the scale score, and the attainment of substantial PTG was indicated by an average score of 4 [79].

The survey includes also the following validated self-reported questionnaires: DASS-21 [80]; General Health Questionnaire—12 items version (GHQ) [81]; Obsessive-Compulsive Inventory—Revised version (OCI-R) [82]; Insomnia Severity Index (ISI) [83]; Suicidal Ideation Attributes Scale (SIDAS) [84]; Severity of Acute Stress Symptoms Adult Scale (SASS) [85]; the Impact of Event Scale—short version (IES) [86]; the UCLA loneliness scale—short version [87]; the Brief-COPE [88]; the Connor-Resilience Scale [89]; the Multidimensional Scale of Perceived Social Support (MSPPS) [90]. Moreover, socio-demographic (i.e., gender, age, civil status, level of education, number of cohabitations, geographical region, living in one of the most severely impacted area, working condition, housing condition, etc.) have been collected through an ad-hoc schedule.

This study is being conducted in accordance with globally accepted standards of good practice, in agreement with the Declaration of Helsinki and with local regulations.

Written informed consents have been collected from participants in order to take part to the online survey. The present study protocol has been reviewed and approved by the Ethical Review Board of the University of Campania “L. Vanvitelli” (Protocol number:0007593/i).
Statistical Analysis

Socio-demographic and clinical characteristics of the global sample have been analyzed using descriptive statistics and frequency tables, as appropriate. Differences in levels of PTG according to the different target groups (i.e., general population, healthcare workers, patients with pre-existing mental disorders, people infected by COVID-19) were evaluated using chi-square with multiple comparisons and ANOVA with Bonferroni corrections.

In order to assess the impact of the duration of lockdown on the different dimensions of post-traumatic growth (i.e., personal strength, relating to others, new possibilities, spiritual life and appreciation for life) multivariate linear regression models were implemented. This statistical approach has been already adopted in previous published papers based on the COMET study [54] and the categorical variable “Week” was entered in the regression models. Several socio-demographic characteristics, including gender, age, working status, having a physical comorbid condition, having a pre-existing mental disorder, civil status, level of education, satisfaction with one’s own life, and with housing conditions, adaptive and maladaptive coping strategies, having been infected by COVID-19 were entered in the models and adjusted for them.

Multiple imputation approach has been used for managing missing data. The level of statistical significance was set at p < 0.05 and statistical analyses were performed using the Statistical Package for Social Sciences (SPSS), version 26.0, and STATA, version 15.

Results

The final sample consists of 20,720 participants, mainly female (71%, N=14,720) and with a mean age of 40.4±14.3 years (Table 1), half of the respondents were in a stable relationship and were living with a partner.

The majority of the sample (67%, N=13,889) did not report any significant improvement in any domain of PTG (Figure 1). Only 4% of participants (N=824) reported a substantial PTG (i.e., >4.0) by the overall scale score. Considering the specific dimensions of PTG, 18% (N=3,739) of respondents achieved a significant post-traumatic growth in the dimensions of appreciation for life and personal strength, while only 4.8% (N=1003) of participants reported a change in spiritual life.

Participants reported the highest levels of growth in the dimension of “appreciation of life” (2.3±1.4), while the lowest level was found in the “spiritual change” (1.2±1.2).

Female participants reported a slightly higher level of PTG in the dimensions of personal strength (p<.002) and appreciation for life (p<.007) compared to male participants, while
no significant association was found with age (Table 2). No significant differences in the levels of PTG were found among healthcare professionals, people infected by COVID-19 and patients with pre-existing mental disorders, compared to the general population (Table 3).

At the multivariate regression models, weighted for the propensity score, only the initial week of lockdown (between April 9 – April 15) had a negative impact on the dimension of “relating to others” of the PTG (B= -.107, 95% CI= -.181 to -.032, p<.005), while over time no other effects were found. However, the duration of exposure to lockdown measures did not influence the other dimensions of PTG (Table 4).

Factors significantly associated with the increase in the levels of PTG include the levels of resilience, with a B coefficient ranging from .025 (95% CI=.023 to .027) for “relating to others”, p<.000) to B=.047 (95%CI=.045 to .049) for “personal strength” (p<.000), the perceived support from family members and friends and the level of education. Furthermore, adaptive coping strategies, such as emotional support (B=.140, 95% CI=.108 to .172, dimension “relating to others”; B=.055, 95%CI=.028 to .083, dimension “new possibilities”; B=.071, 95%CI=.038 to .104; B=.048, 95% CI= .013 to .082, dimension “appreciation for life”), reframing (.208, 95%CI=.182 to .233) and practical support (B=.186, 95%CI=.153 to .218) were significant predictors of several dimensions of PTG, including relating to others, new possibilities and appreciation for life. On the other hand, maladaptive coping strategies, including self-blame (B= -.047, 95%CI= -.073 to -.022) and venting (B= -.043, 95%CI= -.070 to -.016) were associated with a reduction of many dimensions of post-traumatic growth.

Living in one of the most severely hit areas of the pandemic was a negative predictor only for the “New possibilities” (B= -.032, 95%CI= -.064 to -.001), but not for the other dimensions of PTG. Having a pre-existing mental or physical disorder, having being infected by COVID-19, being an healthcare worker did not have any impact on the several dimensions of post-traumatic growth.

Finally, in the different age groups, the probability of having higher levels of post-traumatic growth was found in people aged 55-64 years old, both for the dimension of relating to others (B=.118, 95% CI= .033 to .204) as well as for the dimension of personal strength (B=.122, 95%CI=.033 to .211).

Discussion
This study was conducted to investigate the levels of post-traumatic growth during the first wave of COVID-19 related lockdown in the general population. During the initial phase of the national emergency for the pandemic, Italy was one of the most severely hit areas in Europe, and strict containment measures were issued by the Italian government in order to limit the spread of the virus and its morbidity and mortality rate, since no vaccinations were available [91]. This survey was promoted and disseminated in the Italian general population during the weeks of the first lockdown, a period of uncertainty, fears for the future and exceptional changes in the daily routine. All these socio-cultural factors have contributed to feature the pandemic as a new type of traumatic stressor, which could have an impact on the mental health of the general population. Although several papers have reported increasing levels of anxiety, depressive and stress symptoms in the Italian general population [54], as well as the presence of sleep disorders and of suicidal ideation, a few data are available on the possible positive consequences of the pandemic on the general population. Some studies have found that growth and distress are at opposite ends of the same continuum, from which a negative association was found [92]. Alternatively, growth has been thought to positively coexist with distress, with some authors stating that “the higher the distress, the better the growth” [93]. In the present study, we found that respondents did not report high levels of post-traumatic growth, with only 15% reporting a significant growth at least in one dimension. This data is in line with those found in Hong-Kong, where post-traumatic growth was found in less than 20% of the general population [94,95]. Other studies carried out in China reported levels of post-traumatic growth of up to 50% in at least one domain of PTG. These differences could be due to the divergence in social contexts among countries, in terms of social cohesion, acceptance and satisfaction with the governmental measures for containing the pandemic and the perception of collective identity [96,97]. Therefore, it is of the extreme interest to understand the possible impact of these necessary and unavoidable containment measures on the mental health of the general population, in order to develop appropriate supportive and preventive interventions to mitigate the long-term negative effects of the pandemic on mental health.

Regarding the several PTG dimensions, we found that scores of “appreciation of life” were the greatest., while “spiritual change” was the lowest. These results are in line with those reported by Prati and Pietrantoni (2014), confirming that our findings can be considered representative of the Italian general population.
Another interesting finding is that higher levels of post-traumatic growth during the initial phase of the pandemic were found in female participants. Previous studies carried out during other natural emergencies have found a gender difference in the levels of post-traumatic growth [98]. Although little research has examined the underlying processes for such gender differences in PTG, the role of some cognitive styles, such as rumination, has been proposed [98,99]. In particular, the tendency to ruminate on constructive issues, such as an increased awareness of personal strengths or an appreciation of the importance of social connections, has been suggested as the mechanism leading to the greater reports of PTG [100]. In different groups of traumatized people, such as bereaved parents or women at a high risk for breast cancer, the use of reflective rumination was associated with high levels of post traumatic growth [101-103].

Another potential mediator while processing traumatic events is the type of coping strategies. In fact, we found that using adaptive coping strategies, such as planning, practical support and reframing, predicted higher levels of post-traumatic growth. This finding is in line with previous COVID-related data [54, 104] but also with other studies carried out on factors moderating the impact of traumatic events [100, 105, 106]. PTG may be conceptualized as a cognitive adaptive process among those who experience traumatic stress in response to a disaster, in terms of a positive reinterpretation and positive reframing of the negative experience. However, the use of adaptive coping strategies can sustain and booster this process and it is therefore essential to promote the dissemination of psychosocial interventions aiming to teach and improve adaptive coping strategies in the general population.

Contrary to what we expected, we did not find a significant effect of the weeks of lockdown on the levels of post-traumatic growth, except for the dimension of “searching new possibilities”. This finding is particularly striking if we consider that the levels of stress and of psychiatric symptoms tended to increase over time [54]; it may be that PTG is not related to the duration of the traumatic event, but it is related to the nature of the trauma and to the personality traits and characteristics of the individual [107]. Of course, this interpretation deserves more studies. Furthermore, patients with pre-existing severe mental disorders did not show significantly lower levels of PTG, compared to the general population. This was an unexpected finding, which should be due to the ability, skills and personal resources of patients to adapt to the “new” life routine posed by the pandemic. Moreover, a possible time-lead effect should explain this
finding, being the levels of PTG quite high at the initial phase of the pandemic, and it should be reduced over the following months.

The present study has some limitations, which are hereby acknowledged. First, the online snowball sampling methodology may have led to a selection bias, with only those interested in the psychological consequences of the pandemic willing to participate [108]. Second, the cross-sectional design of the survey prevents us to delineate any causal relationship between the selected variables. Finally, several variables, such as social cohesion, national identity and interpersonal trust, personality traits and cognitive styles should have had an impact on the levels of post-traumatic growth [107, 109].

Conclusions

The assessment of the levels of post-traumatic growth in the general population during the initial phase of the national health emergency is of great importance for the development of ad hoc supportive and preventive psychosocial interventions [110-113]. It has been repeatedly stated that the pandemic will have longstanding, and far-reaching, consequences on global mental health and wellbeing to the whole population, regardless of age and gender [114-117]. From a public health perspective, the identification of protective factors is crucial for developing ad-hoc tailored interventions and for preventing the development of full-blown mental disorders in large scale [118-121]. From a clinical practice perspective, the promotion of supportive interventions aiming to improve the levels of resilience, the adaptive coping strategies and the levels of post-traumatic growth should be prioritized in order to mitigate the detrimental effects of the pandemic.
