Postnatal Brain Growth Assessed by Sequential Cranial Ultrasoundography in Infants Born <30 Weeks’ Gestational Age

Background and Purpose: Brain growth in the early postnatal period following preterm birth has not been well described. This study of infants born at <30 weeks’ gestational age and without major brain injury aimed to accomplish the following: 1) assess the reproducibility of linear measures made from cranial ultrasoundography, 2) evaluate brain growth using sequential cranial ultrasoundography linear measures from birth to term-equivalent age, and 3) explore perinatal predictors of postnatal brain growth.

Materials and Methods: Participants comprised 144 infants born at <30 weeks’ gestational age at a single center between January 2011 and December 2013. Infants with major brain injury seen on cranial ultrasoundography or congenital or chromosomal abnormalities were excluded. Brain tissue and fluid spaces were measured from cranial ultrasoundography performed as part of routine clinical care. Brain growth was assessed in 3 time intervals: <7, 7–27, and >27 days’ postnatal age. Data were analyzed using intraclass correlation coefficients and mixed-effects regression.

Results: A total of 429 scans were assessed for 144 infants. Several linear measures showed excellent reproducibility. All measures of brain tissue increased with postnatal age, except for the biparietal diameter, which decreased within the first postnatal week and increased thereafter. Gestational age of ≥28 weeks at birth was associated with slower growth of the biparietal diameter and ventricular width compared with gestational age of <28 weeks. Postnatal corticosteroid administration was associated with slower growth of the corpus callosum length, transcerebellar diameter, and vermis height. Sepsis and necrotizing enterocolitis were associated with slower growth of the transcerebellar diameter.

Conclusions: Postnatal brain growth in infants born at <30 weeks’ gestational age can be evaluated using sequential linear measures made from routine cranial ultrasoundography and is associated with perinatal predictors of long-term development.

Abbreviations: AHWM = anterior horn width; BPD = biparietal diameter; BW = birth weight; CCL = corpus callosum length; cUS = cranial ultrasoundography; GA = gestational age; NEC = necrotizing enterocolitis; PMA = postmenstrual age; PNA = postnatal age; TEA = term-equivalent age; TCD = transcerebellar diameter

Preterm infants are at risk of long-term neurodevelopmental impairment related to perinatal brain injury and altered brain maturation.1,2 The optimal technique and timing of neuroimaging for identifying high-risk infants is under debate.3 While early and sequential cranial ultrasoundography (cUS) can be reliably used to detect major brain injury, it is less sensitive than MR imaging for the more prevalent, diffuse white matter injury associated with preterm birth.1,4,5 Nonetheless, cUS remains the most widely used neuroimaging technique for preterm infants because it is readily available, easily repeatable, and sensitive enough for detecting most major pathology.

In the absence of overt brain injury and where MR imaging is not accessible, there is a need to improve the prognostic utility of cUS, to better understand why some preterm infants without major brain injury seen on cUS later develop motor and cognitive impairments.1,6 Most infants born preterm have at least 1 early and 1 later neonatal cUS scan, affording an opportunity to quan-
tify early brain growth as a potential marker of long-term development that has not been fully exploited.7

Linear measures of brain tissue and fluid spaces made from neonatal cUS have been associated with neurodevelopmental outcomes in preterm children.6,9 However, only 2 studies have evaluated early postnatal brain growth using sequential cUS.8,10 In a study of 140 infants born at <29 weeks' gestational age (GA), Roelants et al10 reported normative data for the growth of the corpus callosum length (CCL) and corpus callosum–fastigium length with respect to postmenstrual age (PMA), but they did not relate brain growth with postnatal age (PNA). The study of 61 very-low-birth-weight infants by Anderson et al9 found that slower growth of the CCL between 2 and 6 weeks' PNA was predictive of motor delay and cerebral palsy at 2 years; however, this study included infants with major brain injury.

To explore further the usefulness of cUS in assessing brain growth in preterm infants without major brain injury, we aimed to achieve the following: 1) assess the reproducibility of linear measures of brain tissue and fluid spaces made from cUS, 2) evaluate brain growth with respect to PNA using sequential cUS linear measures from birth to term-equivalent age (TEA), and 3) explore the associations between perinatal variables and postnatal brain growth measured by cUS.

MATERIALS AND METHODS

Study Participants

One hundred forty-nine infants born at <30 weeks' GA at The Royal Women’s Hospital, Melbourne, Australia, between January 2011 and December 2013, were recruited into a prospective longitudinal study of neuroimaging, neurobehavior, and long-term development.11 Infants with congenital or chromosomal anomalies known to affect neurodevelopment were excluded. For the current study, 5 infants with major preterm brain injury detected on cUS were also excluded, including infants with grades III or IV intraventricular hemorrhage, posthemorrhagic ventricular dilation, and cystic periventricular leukomalacia, leaving 144 infants for analysis.12,13

The study received institutional approval from the Human Research Ethics Committee of the hospital, and written informed consent was obtained from parents of all participants.

Cranial Ultrasonography

CUS was performed as part of routine clinical care using a Logiq 9 Ultrasound System and an 8-MHz broadband curvilinear transducer (GE Healthcare, Milwaukee, Wisconsin). Standard images were acquired through the anterior fontanel (5 images in different coronal planes, an image in the midsagittal plane, and 2 images in different parasagittal planes both on the left and right) and the mastoid fontanel (1 image in the coronal plane). As per local protocol for the surveillance of preterm brain injury, infants born at <30 weeks' GA were scanned on, or around, days 7, 28, and 60 PNA. Infants born at <28 weeks’ GA were also scanned on, or around, day 1 PNA. Additional scans were performed depending on clinical need. The current study included all neonatal scans performed from birth to TEA (<42 weeks' PMA).

Nineteen linear measures of brain tissue and fluid spaces were explored on the basis of potential clinical importance, ease of recognition of anatomic landmarks on standard imaging planes, and evaluation of their reproducibility (Fig 1). A neonatologist (R.C.) blinded to the clinical course of study participants and with 4 years’ experience in performing cUS obtained measurements using electronic calipers on stored digital images (Synapse; Fujifilm Medical Company, Minato-Ku, Japan). Thirty scans (7%) were randomly selected to assess the reproducibility of the linear measures. Measurements were made by the same observer (R.C.) twice, at least 1 month apart, and once by another observer (S.R.) with 20 years’ experience in performing cUS.

Perinatal Predictors of Long-Term Neurodevelopment

Perinatal variables were chosen a priori on the basis of their known associations with brain injury and long-term neurodevelopmental outcomes following preterm birth.14 These included GA at birth (determined by first-trimester ultrasonography when available or by menstrual history), birth weight SD score (BW z score), sex, multiple gestations, chorioamnionitis (confirmed by placental histology), antenatal corticosteroids (any number of doses of betamethasone) and magnesium sulfate (for maternal or fetal indications), bronchopulmonary dysplasia (defined by oxygen requirement at 36 weeks’ PMA), postnatal corticosteroids, confirmed sepsis (blood or CSF culture-positive and the use of antibiotics for ≥5 days) and/or necro-
tizing enterocolitis (NEC; defined by stage II or higher modified Bell criteria), and low-grade intraventricular hemorrhage (grades I or II) seen on cUS (defined by Papile classification). 13,15

**Data Analysis**

Data were analyzed using STATA, Version 13.1 (StataCorp, College Station, Texas). Intra- and interobserver agreement was assessed by the intraclass correlation coefficient. Linear measures with both intra- and interobserver intraclass correlation coefficients of >0.80 were considered for inclusion in further analyses. Brain growth (or rate of change) with respect to PNA was assessed using mixed-effects linear regression fitted to all the sequential measurements from all individuals, with PNA as the time variable and a random effect for an individual fitted with an unstructured covariance matrix. The model included a random effect to account for multiple measurements for each infant, with a fixed effect of time. First, overall brain growth was assessed from birth to TEA using a single time variable. Brain growth was then assessed within 3 time intervals to reflect the timing of our routine cUS by fitting separate effects of time in the periods <7, 7–27, and >27 days’ PNA. Analyses were repeated with adjustment for GA, BW z score, and sex. Associations between perinatal variables and brain growth with respect to PNA (fitting a single effect of time from birth to TEA) were explored separately by including an interaction between the perinatal variable and PNA in the mixed-effects linear regression model. Continuous variables were dichotomized for this analysis: GA group (<28 weeks or 28–29 weeks) and BW z score group (<–2 or ≥–2 SDs from the mean). Analyses were repeated with adjustment for GA, BW z score, and sex, with the exception that GA and the BW z score were not adjusted for when exploring the effect of the GA group and BW z score group, respectively. Measurements of the left and right anterior horn widths (AHWs) included the germinal layer hemorrhage when present. Consequently, all analyses involving the AHW were restricted to infants without an ipsilateral intraventricular hemorrhage, to eliminate the influence of the germinal layer hemorrhage on the generalizability of results with respect to rates of change of the AHW with PNA.

**RESULTS**

Characteristics of the 144 infants included in the current study are presented in Table 1. In the 144 infants, 429 scans were performed from birth to TEA. The mean number of scans per infant was 3 (range, 1–8). For the 77 infants born at <28 weeks’ GA, 291 scans were assessed (mean, 3.8; range, 1–8 per infant), and 138 scans for the 67 infants born at ≥28 weeks’ GA (mean, 2.1; range, 1–6 per infant). Almost two-thirds (n = 272; 63%) of the scans were performed at <28 days’ PNA, but most infants had scans up to 33 weeks’ PMA.

**Intra- and Interobserver Reproducibility**

Intra- and interobserver intraclass correlation coefficients are shown in Table 2. Eight linear measures, 4 of brain tissue (biparietal diameter [BPD], CCL, transcerebellar diameter [TCD], and vermis height) and 4 reflecting fluid spaces (interhemispheric distance, left and right AHWs, and ventricular width), had intraclass correlation coefficients of >0.8 both between and within observers and were used to evaluate brain growth.
Brain Growth with Respect to Postnatal Age

There was evidence that all linear measures of brain tissue increased with PNA, before and after adjustment for GA, BW z score, and sex, overall and within the 3 time intervals, except for the BPD, which decreased within the first postnatal week (Fig 2 and On-line Table). Faster rates of growth of the BPD, TCD, and vermis height were observed after 27 days’ PNA compared with 7–27 days’ PNA; however, the rate of growth of the CCL more than halved after 27 days’ PNA compared with 7–27 days’ PNA (Fig 2 and On-line Table).

Rates of change of linear measures of fluid spaces were variable within the first postnatal week, with little evidence of an association between linear measures and PNA (Fig 2 and Online Table). The interhemispheric distance and ventricular width increased after the first postnatal week, with faster rates of change after 27 days’ PNA (1.5 and 2.7 times, respectively) compared with 7–27 days’ PNA. Although the rates of change for the AHW appeared to decrease with successive time intervals, there was little statistical evidence of an association between the AHW and PNA, except for the right AHW between 7 and 27 days’ PNA.

Associations between Perinatal Variables and Postnatal Brain Growth

There was strong evidence of associations between many of the perinatal variables and brain growth with respect to PNA, which remained after adjustment for GA, BW z score, and sex (Table 3). Infants born at 28–29 weeks’ GA showed slower growth of the BPD and ventricular width than infants born at <28 weeks’ GA. Postnatal corticosteroid administration was associated with slower growth of the CCL, TCD, and vermis height, and bronchopulmonary dysplasia was associated with slower growth of the CCL and TCD. Infants with a BW z score <−2 SDs below the mean showed slower growth of the CCL than infants with BW ≥−2 SDs below the mean. Sepsis and/or NEC and antenatal corticosteroid administration were associated with slower growth of the TCD.

DISCUSSION

In this study of early postnatal brain growth in infants born at <30 weeks’ GA and without major brain injury, several linear measures of brain tissue and fluid spaces were reliably made from routine clinical cUS scans. Most linear measures of brain tissue increased with PNA, but rates of change were more variable for the fluid spaces. Several perinatal variables related to long-term development were associated with postnatal brain growth. Bronchopulmonary dysplasia and postnatal corticosteroid administration were associated with slower growth of the CCL and TCD, and postnatal corticosteroid administration was also associated with slower growth of the vermis height. Sepsis and/or NEC were associated with slower growth of the TCD.

Measurements of brain growth for use in clinical practice should be simple to obtain and reproducible. The cUS linear measures explored in this study had well-defined anatomic landmarks on standard imaging planes obtained during routine clinical care, and several showed excellent intra- and interobserver reproducibility, as also shown by others.8,10,16,17

Although cUS affords an opportunity to make sequential measurements from birth, there are limited published data relating to postnatal brain growth in preterm infants. To our knowledge, this study is the first to describe the growth of the BPD in the early postnatal period following preterm birth using sequential cUS. We speculate that the decreasing size of the BPD in the first postnatal week found in the current study may relate to a reduction in brain-water in the immediate postnatal days rather than deformational changes in head shape.18 Growth of the BPD between 7 and 27 days was slower (1.30 mm/week PNA) than after the first 27 days (1.72 mm/week PNA), from which time postnatal growth of the BPD approximates to expected fetal growth (2.10 mm/week PMA) as reported from cross-sectional data by Kurmanavicius et al.19 Higher GA at birth related to slower growth of the BPD from birth to TEA, in keeping with normative data for fetal growth of the BPD that demonstrates a slowing of growth with increasing PMA.19,20 However, infants born at <30 weeks’ GA have smaller brains at TEA than term-born controls, and most are likely to have slower rates of brain growth immediately after birth than normally expected in utero.20,21

In the current study, CCL growth was relatively constant from birth to 27 days’ PNA but slowed by half thereafter. Similarly, Anderson et al showed that postnatal growth of the CCL in very-low-birth-weight infants approximated fetal growth (1.4–1.89 mm/week PMA) within the first 2 postnatal weeks but subsequently slowed to approximately half of that expected.22,23 Moreover, the current study found that a BW z score of <−2 SDs was associated with slower CCL growth from birth to TEA, a finding consistent with that of Roelants et al.10 The TCD measured in the fetus, or the neonate in the first postnatal days, is a reliable marker of GA, even with fetal growth restriction, small- and large-for-gestational age fetuses, and multiple gestations (1.25–1.89 mm/week PMA). Two cross-sectional preterm MR imaging studies have reported cerebellar size, but our study is the first to report postnatal growth of the TCD in preterm infants using sequential cUS.20,28 Similar to fetal growth patterns, TCD growth in the current study progressively increased between time intervals. Unlike the TCD, the vermis height increased with PNA at a relatively constant rate of change from birth to TEA, approximating fetal growth (0.55 mm/week PMA).29 Bronchopulmonary dysplasia and postnatal corticosteroids were associated with slower CCL and TCD growth with PNA, and postnatal corticosteroid administration was also related to slower growth of the vermis height. Tam et al reported a similar association between postnatal corticosteroids, a marker of severe bronchopulmonary dysplasia, and impaired cerebellar growth in very preterm infants using serial MR imaging between 32 weeks’ PMA and TEA. In another MR imaging study of very preterm infants scanned at TEA and 7 years, Thompson et al reported an association between postnatal corticosteroids and delayed maturation of the posterior corpus callosum, a region that develops later in gestation and contributes to corpus callosum length. In the current study, sepsis and/or NEC were related to slower growth of the TCD. Sepsis and/or NEC have been associated with preterm white matter injury at TEA, but their relationship with brain growth and maturation in the early postnatal period remains unclear.32 The relationship between antenatal corticoste-

*Adjusted for gestational age, birth weight z score, and sex. P value for the interaction between the perinatal variable and postnatal age.

Brain growth in infants born at <30 weeks’ GA can be assessed using simple and reproducible linear measures made on sequential cUS. Several perinatal variables already shown to be related to long-term development, including GA, BW z score, bronchopulmonary dysplasia, postnatal corticosteroids, and sepsis and/or NEC, were associated with early postnatal brain growth. Further research is needed to evaluate the usefulness of brain growth, as evaluated using sequential cUS linear measures, as a marker of long-term neurodevelopmental outcome.
