Over the past 20 years, there have been significant inroads into understanding the roles of antimicrobial peptides in homeostatic functions and their involvement in disease pathogenesis. In addition to direct antimicrobial activity, these peptides participate in many cellular functions, including chemotaxis, wound healing and even determination of canine coat colour. Various biological and genetic approaches have helped to elucidate the role of antimicrobial peptides with respect to innate immunity and host defense.

Associations of antimicrobial peptides with various skin diseases, including psoriasis, rosacea and atopic dermatitis, have been documented in humans. In the longer term, therapeutic modulation of antimicrobial peptide expression may provide effective new treatments for disease.

This review highlights current knowledge about antimicrobial peptides of the skin and circulating leukocytes, with particular focus on relevance to physiology and disease in companion animals.

Introduction

Antimicrobial peptides (AMPs) are naturally occurring antimicrobials found throughout nature. In mammals, AMPs are expressed by both epithelial cells and phagocytic leukocytes, and they possess broad-spectrum antimicrobial activity against bacteria, fungi and viruses. In addition, AMPs can promote chemotaxis, wound healing and, interestingly, determination of coat colour in dogs (Figure 1). Antimicrobial peptides have been identified and described in all mammals studied, including companion animals. The two major subfamilies of AMPs in mammals are cathelicidins and defensins, which exhibit similar physical properties and many overlapping activities (Figure 2).

Mammalian skin is generally thought of as a thin lining that separates the host from the external world. Despite constant confrontation with pathogens, the incidence of skin infections remains relatively low. The epidermis provides a physical barrier to microbial invasion and prevents favourable niches for pathogens. In the event that this physical barrier is breached, a co-ordinated innate immune response, involving macrophages and neutrophils, is activated to eliminate the invaders. However, this view of innate immunity is incomplete. Recent evidence shows that the epidermis is much more than just a physical barrier. Indeed, epidermal keratinocytes are equipped with pathogen recognition receptors and can detect and respond to potential invaders. This response helps to initiate a co-ordinated inflammatory response, which includes recruitment of leukocytes. Another important element of this defensive response is the induction of AMPs by keratinocytes. This review highlights the current knowledge of AMPs in dogs, cats and humans, with particular relevance to skin biology and disease.

Repertoire of AMPs

Defensins

Defensins are small, cationic peptides that are expressed by certain phagocytic leukocytes and epithelial cells. These peptides possess broad-spectrum antimicrobial activity (Figure 2). The defensins are categorized into three subfamilies, α, β and θ, based on their disulfide bonding array and primary amino acid sequence. Evolutionarily speaking, the β-defensins are the oldest of the defensins, tracing their ancestry back to the horseshoe crabs. The host genomic repertoire of defensins varies greatly between species, in both number of defensins encoded and sequence diversity. The α-defensins have been found in primates, glires and horses, but not in dogs, whereas the β-defensins have been documented in all mammals and some lower order species as well. The θ-defensins are unique in that they are encoded in the genomes of humans and nonhuman primates, although a functional gene product has only been found in nonhuman primates.

A comparative genome analysis of the dog has identified 43 β-defensin genes and pseudogenes. Much of the gene nomenclature has been modelled after putative human orthologues. Canine β-defensins are arranged in...
four gene clusters that correspond to those in rats, mice and humans.\textsuperscript{10} The best-characterized \(\beta\)-defensin cluster in humans is encoded on chromosome 8p23.1, which is syntenic with the \(\beta\)-defensin cluster on chromosome 16 of dogs (Figure 3).\textsuperscript{10} The first canine defensin gene identified was named canine \(\beta\)-defensin-1 (\textit{CBD1}), and appears to encode the orthologue of BD1 in rodents and humans. The remaining canine defensin genes are numbered \textit{CBD102–CBD142} (to correspond roughly to their human counterparts); two additional defensin genes are referred to as canine sperm-associated antigen (\textit{SPAG11c} and \textit{SPAG11e}).\textsuperscript{10} The study by Patil et al.\textsuperscript{10} clearly defines and names all of the defensins in the canine genome. Owing to the already complex nomenclature in the defensin field, we encourage fellow investigators to adopt this scheme as a consistent method of labelling canine defensins to reduce ambiguity and ease the interpretation of data between studies.

**Cathelicidins**

Cathelicidins are AMPs that also possess broad-spectrum activity, yet they exhibit great diversity in both sequence and structure (Figure 2).\textsuperscript{13} Like defensins, the cathelicidin precursor has three domains: a signal sequence, a propeptide domain and a mature peptide at the C-terminus.\textsuperscript{14} However, the unifying feature of cathelicidins is not the sequence of the mature peptide, but the propeptide domain, a region with sequence similarity to the protease inhibitor, cathelin.\textsuperscript{13} The sequence of this propeptide domain is highly conserved across diverse species.\textsuperscript{14,15} In contrast, the mature peptide sequence varies widely between species and can be classified into the following four subfamilies: linear \(\alpha\)-helical; proline- and arginine-rich; tryptophan-rich; or disulphide bond-containing peptides.\textsuperscript{14} In addition to sequence diversity of the mature peptide, there is considerable variability in the number of cathelicidins encoded by genomes of various species.\textsuperscript{15} Humans (LL-37), mice (CRAMP), dogs (K9CATH) and cats (feCath) express a single cathelicidin,
whereas horses, pigs, cows and goats express multiple cathelicidins.\textsuperscript{7,15,16}

Expression patterns of AMPs

Depending on the particular peptide in question, the expression of AMPs is either constitutive or inducible by various stimuli, including inflammation and the presence of pathogens.\textsuperscript{5,17}

Defensins

The β-defensins expressed in human skin include human β-defensin 1 (hBD-1),\textsuperscript{18} hBD-2,\textsuperscript{19} and hBD-3.\textsuperscript{20} Canine skin highly expresses β-defensins CBD1 and CBD103\textsuperscript{6}, the putative orthologues of hBD-1 and hBD-3, respectively.\textsuperscript{10} There is no clear orthologue of hBD-2. Indeed, due to differences in gene structure and tissue expression, CBD102 is not similar to hBD-2.\textsuperscript{10} The CBD102 gene contains three exons,\textsuperscript{10} and analysis of mRNA from multiple tissues indicates that CBD102 expression is limited to the testes (B.C.L. and C.L.B., unpublished data), whereas the gene encoding hBD-2 (named DEFB4) has two exons and is broadly expressed in many tissues, including human skin and colon.\textsuperscript{18,21} Expression of feline β-defensin 103 (feBD103) expression has been identified in cat skin (B.C.L. and C.L.B., unpublished data).

Initially, hBD-1 was identified in haemofiltrate from dialysis patients and subsequently localized to epithelial cells from many tissues, including pancreas, kidney and skin.\textsuperscript{18,22,23} Expression of hBD-1 is constitutive. The promoter region of hBD-1 lacks transcription factor binding sites often involved in inflammation, such as nuclear factor-κB or AP-1 (activator protein-1),\textsuperscript{24} and the hBD-1 transcript is not upregulated during inflammation.\textsuperscript{21} In contrast, baseline expression of hBD-2 is low in human keratinocytes, but can be upregulated with inflammation or pathogenic stimulation.\textsuperscript{19,25,26} Analysis of the promoter region of hBD-2 has revealed two functional nuclear factor-κB binding sites that are responsible, in part, for its upregulation.\textsuperscript{27} Another β-defensin that exhibits inducible expression in human skin is hBD-3, the orthologue of CBD-103 in dogs. Expression of hBD-3 can be induced by tumour necrosis factor-α or contact with bacteria, and in wound-healing responses.\textsuperscript{26,28}

Studies have begun to explore β-defensin expression and function in dogs. Expression has been identified in the testes,\textsuperscript{29} kidney, palatine tonsil, trachea, lung, gastrointestinal tract, liver, spleen, peripheral blood mononuclear cells, bone marrow and skin (Figure 4).\textsuperscript{4,6,30–32} To evaluate possible induced β-defensin expression, canine primary tracheal epithelial cells were treated with both lipopolysaccharide and canine respiratory coronavirus; however, neither stimulus was sufficient to upregulate CBD103 expression.\textsuperscript{32} Further studies are needed in order to understand patterns and regulation of canine defensin expression more fully.

Cathelicidins

Human cathelicidin, LL-37, exhibits constitutive and inducible expression in many different cell types. High levels of LL-37 are found in the bone marrow, and the peptide localizes to specific granules in the neutrophil.\textsuperscript{33} Although constitutive LL-37 expression is very low in...
keratinocytes, treatment with 1,25-(OH)2 vitamin D3 induced LL-37 mRNA expression 100-fold over baseline. Vitamin D3 also induces LL-37 expression in monocytes and macrophages, and can lead to enhanced intracellular killing and promote autophagy in the co-ordinated killing of Mycobacterium tuberculosis. This responsiveness to vitamin D3 involves the vitamin D3 responsive element (VDRE) in the 5' promoter region of the human cathelicidin gene. When comparing cathelicidin genes across species, the VDRE is conserved among primates, but is not present in other species, including mice, dogs and cats.

Canine cathelicidin, K9CATH, is expressed in epithelial cells and leukocytes. High expression is seen in bone marrow, and lower levels are present in the gastrointestinal tract, liver, spleen, testes and skin. The 5' promoter region of K9CATH does not contain any VDRE sequences, suggesting that this gene will not respond to vitamin D3. This suggests that topical vitamin D3 application to canine skin may not be clinically effective in increasing cathelicidin expression. Similar to its canine orthologue, feline cathelicidin, feCATH, is highly expressed in the bone marrow. The peptide immunolocalizes to neutrophils, with lower levels of expression detected in the skin. As in the canine gene, a VDRE sequence was not observed in the 5' promoter region of the gene.

**Activity of AMPs**

**Antimicrobial activity**

Cationic AMPs are generally thought to exert their antimicrobial effect through permeabilization of target microbial membranes. The positively charged arginine and lysine residues of AMPs interact favourably with the negatively charged microbial membranes via electrostatic interaction. This interaction has been demonstrated both with artificial vesicles composed of anionic lipids and with bacteria, such as *Escherichia coli*. Following charge-mediated interaction of AMPs and the membrane, the amphipathic nature of the peptide promotes hydrophobic integration into the membrane. The result is initial formation of pores, which can dissipate electrochemical gradients, and at high concentrations of AMP, severe membrane disruption and a release of intracellular contents (Figure 5).

Interestingly, recent data have provided evidence for a specific intracellular target for some defensins against Gram-positive bacteria. Wei et al. synthesized several defensins using ε-amino acids, rather than the natural ε-isomers. Each defensin peptide retained equal activity against Gram-negative bacteria, presumably because the mechanism described above involving pore formation is independent of stereochemistry. In contrast, the ε-enantiomers lost antimicrobial activity against *Staphylococcus aureus*, indicating the importance of peptide chirality for activity against Gram-positive bacteria. Subsequent studies demonstrate that Lipid II, an essential component for bacterial cell wall biosynthesis, is the target for (at least) some defensins against Gram-positive bacteria (Figure 5). These insights into specific mechanisms of antimicrobial killing may help propel development of novel therapeutics.

Recent studies have focused on the antimicrobial activity of canine AMPs and pathogens that frequently complicate chronic skin disease in dogs. Canine cathelicidin displayed potent, broad-spectrum antimicrobial activity against various pathogens, including *S. aureus*, *E. coli* and *Listeria monocytogenes*. In addition, Fazakerley et al. demonstrated equal antimicrobial activity of synthetic hBD-3 against *Staphylococcus pseudintermedius* isolated from both healthy canine skin and dogs with atopic dermatitis.

**Bacterial resistance**

In retaliation to the antimicrobial defenses elaborated by a given host, pathogens have developed methods of resistance. Proteolytic degradation of AMPs is one mechanism by which bacteria evade innate immune measures. The human cathelicidin, LL-37, can be proteolytically degraded by bacterial proteases, including SpeB of *Streptococcus pyogenes* and elastase B of *Pseudomonas aeruginosa*. *Staphylococcus aureus* expresses a metalloproteinase, aureolysin, which can also degrade LL-37. The intramolecular disulfide bonds of defensins help protect this class of AMP from proteolysis.

In addition to degradation, some pathogens express proteins that can directly bind and neutralize AMPs. Lyogenic strains of *S. aureus* produce staphylokinase, which binds defensins and inhibits their ability to kill. Likewise, streptococci produce a protein called streptococcal inhibitor of complement that can neutralize defensins.

Many bacteria have the ability to modulate the overall charge of their membranes, making them less anionic, and hence resistant to cationic AMPs. These enzyme-mediated modifications of lipopolysaccharide were first described in the Gram-negative pathogen *Salmonella Typhimurium*. The external bacterial membranes of the Gram-positive bacteria *S. aureus* and streptococci contain negatively charged teichoic acids. However, through the addition of positively charged ε-alanine esters to teichoic acids, *S. aureus* and streptococci can repel the electrostatic attraction of cationic peptides, protecting the bacteria from AMPs. *Staphylococcus aureus* can modify the anionic phosphatidylglycerol on the bacterial membrane through the addition of cationic L-lysine. These examples of bacterial countermeasures represent ongoing coevolution of host-pathogen interactions. Insights into the molecular mechanisms of resistance to AMPs may aid in development of future therapeutics.

**Chemotaxis**

Investigations into the chemotactic activity of defensins and cathelicidins for leukocytes have helped to establish a link between AMPs and the adaptive immune system. Leukocytes are attracted by and migrate towards a gradient of AMPs expressed at the site of infection. In humans, neutrophil-derived defensins and LL-37 can chemotact monocytes, naive T cells and immature dendritic cells. The human β-defensins, including hBD-2 and hBD-3, expressed at the epithelial surface have the ability to chemoattract immature dendritic cells and memory T cells through the chemokine receptor CCR6. To gain insight into the structure–function relationship of these β-defensins, truncation mutants and
peptides lacking a complete disulfide array were generated. The data support the idea that both the tertiary structure surrounding the N-terminus and specific residues at this site mediate the interaction between hBD-3 and CCR6. This structure–function relationship has been further substantiated using the mouse orthologue of hBD-3, Defb14. Finally, hBD-2 and hBD-3 have been shown to be chemotactic for monocytes through CCR2. It will be important to evaluate the chemotactic properties of canine and feline orthologues of the hBD-3, because it will provide increased knowledge of the interactions between AMPs and adaptive immunity, as well as providing insight into the structure–function relationships of β-defensins.

Coat colour

Besides serving host defense functions, recent investigations have implicated defensins in dominant black coat colour in dogs. Coat colour in mammals is primarily determined by the interaction of the Agouti peptide with the melanocyte receptor, Mc1r (Figure 6). Constitutive signalling by Mc1r on the surface of melanocytes results in the production of eumelanin, or black pigment. The Agouti peptide can bind Mc1r and antagonize Mc1r signalling, resulting in the production of pheomelanin, or red/yellow pigment within melanocytes. Differential signalling and genetic variation in Agouti and Mc1r account for much of the variation found in mammalian coat colour. In dogs, however, the dominant black coat colour, seen in breeds such as Labrador retrievers, could not be explained by simple interactions between Agouti and the Mc1r receptor.

In 1957, Little hypothesized that dominant black coat colour in the domestic dog was due to an unusual allele of Agouti. Subsequent studies of dominant black colour proved that there is a separate gene, independent of Agouti, that is responsible for the phenotype, an allele in the canine genome termed the K locus. In 2007, Candille and colleagues identified CBD103 as the gene responsible for the dominant black coat colour using link-
age and association mapping. Specifically, a variant of CBD103, referred to as CBD103\textsuperscript{D\textsubscript{G23}}, was found to be responsible for dominant black coat colour. Compared with CBD103, CBD103\textsuperscript{D\textsubscript{G23}} has a three base-pair deletion, resulting in omission of glycine residue 23 at the N-terminus of the mature defensin peptide.\textsuperscript{4} As a result, the CBD103\textsuperscript{D\textsubscript{G23}} variant peptide has the ability to bind to the Mc1r with high affinity, working as a neutral antagonist, thus preventing Agouti from binding and inhibiting this receptor.\textsuperscript{4} Binding of CBD103\textsuperscript{D\textsubscript{G23}} allows unabated signalling from Mc1r to synthesize eumelanin, or black pigment.\textsuperscript{4} This relationship between defensins and coat colour was quite unexpected and implies new possibilities for noncanonical functions of defensins, independent of innate immunity.

Reproduction
Defensins play an important role in sperm maturation, capacitation and adherence to uterine mucosal epithelial cells. As sperm migrate through the specialized regions of the epididymis, their surfaces are modified by the adsorption of various proteins made by epididymal cells, including certain \(\beta\)-defensins.\textsuperscript{74–76} For example, \(\beta\)-defensin 126 (DEFB126) is important for mobility of primate sperm through cervical mucus and binding to oviductal epithelial cells, which provides a reservoir of viable sperm for fertilization.\textsuperscript{77,78} Manipulations of sperm that resulted in loss, masking or alteration of DEFB126 resulted in a reduced ability of the sperm to traverse cervical mucus and bind oviductal epithelial cells.\textsuperscript{77,78} A recent study reported that a genetic variant in DEFB126 is common in humans and is associated with subfertility.\textsuperscript{79}

Genetic variation of AMPs

Genetic organization: gene copy-number polymorphism
Most mammalian genes are diploid, meaning that one copy is inherited maternally and another copy is inherited paternally, yielding a total of two gene copies per genome. However, recent investigations into genomic structure have identified many regions of genomic DNA that are present in multiple copies rather than diploid. Remarkably, for some regions the number of copies is variable from individual to individual.\textsuperscript{80} This type of genetic variability exists not only in humans, but also in dogs, and is referred to as copy-number variation.\textsuperscript{81} Interestingly, the human \(\beta\)-defensin cluster on chromosome 8p23.1, including the genes that encode hBD-2 and hBD-3, have undergone duplication events whereby this cluster repeats more than once on a given chromosome, allowing for a total gene copy-number greater than two.\textsuperscript{82,83} In dogs, the orthologous gene cluster of \(\beta\)-defensins on chromo-

some 16, including CBD103, also exhibits gene copy-number variation (Figure 3), although the extent of variation and breeds that specifically vary in copy number have yet to be reported. The relationship between gene copy-number variation and disease is being intensively studied. Disorders associated with β-defensin gene copy number are discussed in the following section.

**Antimicrobial peptides and disease**

**Psoriasis**

Psoriasis is a common chronic inflammatory skin disease of humans that affects as many as 1–2% of the population in the USA. With the exception of a mouse model, psoriasis has not been recognized in other species, and it is not a disease of dogs or cats. However, salient features of this human disease provide an opportunity to illustrate roles of antimicrobial peptide in chronic inflammatory disorders. Psoriatic patients have overt skin lesions, but these lesions are rarely infected, and the psoriatic scales overlying the lesions are especially rich in AMPs. High levels of hBD-2, hBD-3 and LL-37 have been extracted from the psoriatic scales, and epidermal mRNA expression is significantly higher in lesional skin when compared with either nonlesional skin or healthy skin from control subjects. The increased AMP expression and incorporation into the psoriatic scales is thought to prevent infection. On the contrary, the increased AMP expression could also exacerbate disease due to non-antimicrobial activities of AMPs, such as chemotaxis and DNA binding.

In addition to the increased AMP expression in psoriasis, Hollox et al. have identified an association between psoriatic patients and increased gene copy number. In two separate population cohorts, individuals with six or more gene copy numbers in the β-defensin cluster on chromosome 8 (including hBD-2 and hBD-3) had an increased risk of developing psoriasis. On the contrary, individuals with two or three copies of the β-defensin cluster had a reduced risk of developing psoriasis.

**Atopic dermatitis**

Atopic dermatitis (AD) is a chronic inflammatory skin disease due to an allergic response to nonpathogenic environmental antigens, affecting upwards of 10% of human and canine populations. Clinical and histological similarities between human and canine AD allow researchers to make applicable comparisons. A similarity amongst human and canine patients with AD is the presence of a dysfunctional epidermal barrier. Secondary bacterial infections, Staphylococcus pseudintermedius in dogs, can exploit the dysfunctional barrier, colonizing and complicating skin lesions of AD patients.

Ong et al. demonstrated reduced expression of LL-37 and hBD-2 in AD lesional skin when compared with healthy and psoriatic skin. To study the mechanism of reduced AMP expression, the investigators exposed keratinocytes in culture to the Th2 cytokines interleukin-4 (IL-4) and interleukin-13 (IL-13), both of which are known to be overexpressed in AD lesional skin. Treatment of keratinocytes with IL-4 and IL-13 reduced the expression of hBD-2, even when co-incubated with the proinflammatory cytokine, tumour necrosis factor-α. Another study of AD skin lesions revealed that hBD-3, known to have anti-staphylococcal activity, was also reduced in AD lesional skin due to the presence of IL-4 and IL-13. In addition, it has been observed that AD patients have reduced mobilization of hBD-3, predisposing them to S. aureus infection. However, a recent study by Harder and colleagues demonstrates increased AMP expression in patients with AD when compared with nonlesional skin and control subjects. It is possible to conclude that AD patients with severe disease and a history of recurrent skin infections are unable to upregulate AMP fully to levels required to prevent complicating infections.

In canine AD, CBD1 has been shown to have increased expression in lesional and nonlesional skin when compared with healthy control animals. In contrast, lesional and nonlesional skin exhibited reduced expression of CBD103. This reduction of CBD103 expression may predispose dogs with AD to developing secondary S. pseudintermedius infections.

**Conclusions**

Antimicrobial peptides play an important role in host immunity, in particular at the skin–environment interface. Not only do they possess direct antimicrobial activity, but these peptides also play important roles in shaping host microbiota, chemotaxis, lectin binding, pathogen-associated molecular pattern neutralization, reproduction and coat colour in dogs. There is a great degree of variability in terms of the families and numbers of AMPs encoded by the genome of each species. It is likely that the repertoire of AMPs elaborated by each species is a reflection of their environmental niche, mainly the pathogens that they individually encounter. Importantly, altered expression of AMPs in certain disease states, such as canine and human AD, and psoriasis in humans, predisposes the host to secondary infection or exacerbation of ongoing inflammation, respectively. Further studies of AMPs in veterinary species are needed to define the expression of these peptides, determine genetic variations, evaluate antimicrobial activities, as well as other functions, and investigate their role in disease.

Résumé
Au cours de ces 20 dernières années, il y a eu d’importantes avancées de la compréhension des rôles des peptides antimicrobiens dans leurs fonctions homeostatiques et leur implication dans la pathogénie des maladies. En plus de leur activité antimicrobienne directe, ces peptides participent à de nombreuses fonctions cellulaires, comprenant la chimiotaxie, la cicatrisation et même la détermination de la couleur du pelage chez le chien. Des approches biologiques et génétiques variées ont aidé à élucider le rôle des peptides antimicrobiens au niveau de l’immunité innée et des défenses de l’hôte.

Les associations entre les peptides antimicrobiens et diverses dermatoses, incluant le psoriasis, la rosacée et la dermatite atopique ont été documentées chez l’homme. A plus long terme, la modulation thérapeutique de l’expression des peptides antimicrobiens pourraient fournir de nouveaux traitements efficaces de ces maladies.

Cet article passe en revue les connaissances actuelles sur les peptides antimicrobiens de la peau et des leucocytes circulants. Un accent particulier est donné sur la pertinence de la physiologie et des maladies chez les animaux domestiques.
摘要
过去的二十年里，对抗菌肽在机体自我平衡功能和参与发病机制的理解上有重大的研究进展。除直接抗菌活性外，这些多肽参与多种细胞功能，包括趋化性、伤口愈合、甚至决定犬的毛色。各种生物和遗传途径有助于阐明抗菌肽对先天免疫与机体防御的作用。

抗菌肽与各种皮肤疾病的关系，包括银屑病、红斑狼疮（酒糟鼻）和异位性皮炎，人医研究做出了研究。长久来看，抗菌肽治疗表现的调节可能提供有效的新治疗方案。

本文回顾了当前皮肤抗菌肽和循环白细胞的知识，特别关注了与伴侣动物生理和疾病的关系。
