ABSTRACT

We present multiepoch observations with the Very Long Baseline Array (VLBA) of SiO maser emission in the ν = 1, J = 1 − 0 transition at 43 GHz from the remnant of the red nova V838 Mon. We modeled the positions of maser spots to derive a parallax of 0.166 ± 0.060 mas. Combining this parallax with other distance information results in a distance of 5.6 ± 0.5 kpc, which is in agreement with an independent geometric distance of 6.1 ± 0.6 kpc from modeling polarimetry images of V838 Mon’s light echo. Combining these results, and including a weakly constraining Gaia parallax, yields a best estimate of distance of 5.9 ± 0.4 kpc. The maser spots are located close to the peaks of continuum at ~225 GHz and SiO J = 5–4 thermal emission detected with the Atacama Large (sub)Millimeter Array (ALMA). The proper motion of V838 Mon confirms its membership in a small open cluster in the Outer spiral arm of the Milky Way.

1. Introduction

V838 Mon is a remnant of a so-called red nova, which erupted in January 2002 (Munari et al. 2002b) and immediately came to prominence in the astronomical community and the public due to the spectacular images of a light echo taken with the Hubble Space Telescope (HST; Bond et al. 2003). This eruption probably resulted from a merger of two (~ 8 M⊙ and ≃ 0.3 M⊙) stars (Tylenda & Sokere 2006), but other mechanisms have also been proposed. Munari et al. (2002a) found a composite optical (post-outburst) spectrum of V838 Mon consistent with a binary system of a cool giant and a hotter stellar companion (see also Wagner & Starrfield 2002; Crause et al. 2003; Kamiński et al. 2009). Late in 2002, the cool giant resembled a late-M type star, while the hot companion appeared to be a B3 V star. The M-type star is naturally assumed to be the successor (remnant) of the outbursting star. More recent spectroscopic observations by Loebman et al. (2015) have classified the cool star as an L3 supergiant with an effective temperature of ~ 2000 − 2200 K. The separation between the two components was first estimated to be 28 AU based on the assumption that V838 Mon is an eclipsing binary (Munari et al. 2007). This assumption has been proven to be incorrect and a system separation of ~250 AU was found instead (Tylenda et al. 2009).

Several scenarios have been proposed to explain the nature of the 2002 eruption (see the extended discussion in Tylenda & Sokere 2006), although the observational data illustrate that a stellar-merger event is the most viable explanation. In this scenario, the progenitor of V838 Mon was likely a triple or higher order system dominated by two B-type stars (the outbursting star and the B3V companion; Tylenda & Sokere 2006). A low-mass companion might have entered in a highly eccentric orbit and finally merged with the primary.

Afşar & Bond (2007) discovered that V838 Mon belongs to a sparse open cluster of young (≤ 25 Myr) B-type stars. A diffuse molecular cloud within the echo region was revealed in CO single-dish radio observations by Kamiński et al. (2011). This cloud is thought to be interstellar in nature, consisting of material that remained after the formation of the cluster to which V838 Mon belongs.

The immediate surroundings of V838 Mon are rich in molecular gas. Optical and infrared spectroscopy reveal a multitude of atomic lines and molecular bands with very complex kinematics (Tylenda et al. 2011). Part of this neutral cool gas was lost either during or just before the merger, as in other Galactic red novae (Kamiński et al. 2018). Some of the absorption features of V838 Mon indicate the presence of ongoing mass loss from the coalesced star (Kamiński et al. 2009).

Searches for maser emission from oxygen-rich molecules (SiO, H2O, and OH) and hydrogen recombination lines have been conducted toward V838 Mon. Deguchi et al. (2005) made the first detection of SiO maser emission (J = 1 − 0, ν = 1 and 2) at 43 GHz with the Nobeyama 45-meter telescope in 2005, which was three years after the outburst. Claussen et al. (2007) reported follow-up SiO maser observations taken with the Very Large Array (VLA), the Green Bank Telescope (GBT), and the Very Long Baseline Array (VLBA). The maser emission observed with the VLA and

Article number, page 1 of 12
the GBT showed variations in flux density superimposed on a rising trend (reaching a maximum of about 8 Jy) over a ≈900-day timescale, after which the flux started to decline. The VLA spectra showed one and two features in the \( v = 2 \) and \( v = 1 \) transitions, respectively, at LSR velocities near 54 km \( \text{s}^{-1} \). However, results from the VLBA observations have not been published.

More recently, the same SiO maser lines were observed using the Effelsberg 100m telescope in October, 2013 and in January, 2017. It was found that between the two epochs the \( v = 2 \) line declined from \( \approx 0.3 \) Jy to <0.1 Jy, and the \( v = 1 \) line declined from \( \approx 2 \) Jy to \( \approx 1 \) Jy. This is consistent with the gradual decline of flux density which started in early 2006, as reported by Claussen et al. (2007).

The SiO \( v = 1 \), \( J = 2 \rightarrow 1 \) maser transition at 86 GHz was also detected in this source with the 45m telescope at Nobeyama (Deguchi et al. 2009) and more recently with the IRAM-30m telescope (Kamiński et al. 2018). In addition, interferometric observations at millimeter/submillimeter wavelengths using the Submillimeter Array (SMA) revealed lines of CO, SiO, SO, SO\(_2\), and H\(_2\)S covering a very broad velocity range (\( \sim 400 \) km \( \text{s}^{-1} \); Kamiński et al. 2018). These molecular transitions trace thermal emission from the merger ejecta and are orders of magnitude weaker in peak intensity than the SiO maser lines.

Originally the distance to V838 Mon was uncertain, with estimates ranging from 6 to 10 kpc (Bond et al. 2003; Tylenda 2004; Munari et al. 2005). Based on the geometry of the light echo seen in polarimetric images taken with the HST, Sparks et al. (2008) derived a distance of 6.1±0.6 kpc. This value has been adopted by various authors when deriving the properties of the remnant.

In this paper, we report new VLBA observations of the 43 GHz SiO maser transitions toward V838 Mon. The phase-referencing technique was used to provide accurate astrometry. The VLBA observations are presented in Section 2 and their analysis in Section 3. The astrometric parameters and the distance and proper motion to the source are derived in Section 4. Over the course of the VLBA observations, the Gaia mission published its second data release (Gaia DR2; Gaia Collaboration et al. 2018; Lindegren et al. 2018). We thus also compare our astrometry with that provided by Gaia. We discuss the parallax, position, and proper motions of V838 Mon in Section 5, as well as SiO thermal emission detected in new Atacama Large (sub)Millimeter Array (ALMA) observations. Finally, we present our conclusions in Section 6.

### Table 1. VLBA observed epochs

### 2. Observations and data reduction

#### 2.1. VLBA observations

V838 Mon was observed with the VLBA for a total of 7 epochs between October, 2017 and March, 2019 (Table 1). The observations were taken at 43 GHz with 4 intermediate frequency (IF) bands of 16 MHz bandwidth. Except for the first epoch, two of these IFs were centered at the \( v = 1, J = 1 \rightarrow 0 \) and \( v = 2, J = 2 \rightarrow 0 \) SiO maser transitions, at 43122.080 MHz and 42820.582 MHz, respectively (Müller et al. 2013), and correlated with a channel spacing...
of 31.25 kHz (0.2 km s\(^{-1}\)). The first epoch only covered the \(v = 1\), \(J = 1 - 0\) transition. The quasars J0709–0255 (RA=07:09:45.0546, Dec=−02:55:17.496) and J0656–0323 (RA=06:56:11.1206, Dec=−03:23:06.782), in J2000 coordinates, were observed as phase reference calibrators. Observations consisted of alternate scans on the target and one phase-reference calibrator, switching sources every \(\approx 20\) seconds. Blocks of about 30 minutes spent on calibrators distributed over a wide range of elevations were observed at 23.7 GHz every \(\approx 2\) hours during each 7-hr observing run. These scans (the so-called geodetic-like blocks) were used to estimate multiband delays, which are predominantly introduced by residual tropospheric delays and clock errors.

Data calibration was performed using the Astronomical Imaging System (AIPS; Greisen 2003), using a Parseltongue scripting interface (Kettenis et al. 2006). We used procedures that have been widely applied to perform high-frequency astrometry as part of the Bar and Spiral Structure Legacy (BeSSeL) Survey at 22 GHz (Reid et al. 2009). Given the 300 MHz frequency separation between the \(v = 2\) and \(v = 1\) transitions, we derived independent delay and rate solutions for each IF band instead of combining them. These scans (the so-called geodetic-like blocks) were used to estimate multiband delays, which are predominantly introduced by residual tropospheric delays and clock errors.

## 3. Results

We detected maser emission from the \(v = 1\), \(J = 1 - 0\) transition at 6 epochs at LSR velocities from \(\approx 54\) to \(58\) km s\(^{-1}\) with a peak near \(55\) km s\(^{-1}\) (Figures 1 and 2). Poor observing conditions on August 27, 2018 degraded the sensitivity of the array, which resulted in a nondetection of the \(v = 1\) line. Integrated flux density spectra of the maser emission are shown in Figure 1.

The \(v = 2\), \(J = 1 - 0\) was marginally detected only on January 13, 2018, with an integrated flux density of \(0.10 \pm 0.03\) Jy at 55.3 km s\(^{-1}\). This line was not detected in the last 5 epochs.

The peak flux density of the \(v = 1\) transition, detected with Effelsberg in January, 2017, was 1.2 Jy, that is, almost two times stronger than we see with the VLBA. This variation in the maser intensity is more pronounced than observed before (Claussen et al. 2007). In order to investigate this in more detail, we performed a phase self-calibration, using the velocity channel with the peak flux. The flux density measured in the resulting maps from all epochs after the \(v = 1\) transition, detected with Effelsberg in January, 2017, was 1.2 Jy, that is, almost two times stronger than we see with the VLBA. This variation in the maser intensity is more pronounced than observed before (Claussen et al. 2007). In order to investigate this in more detail, we performed a phase self-calibration, using the velocity channel with the peak flux. The flux density measured in the resulting maps from all epochs after the \(v = 1\) transition, detected with Effelsberg in January, 2017, was 1.2 Jy, that is, almost two times stronger than we see with the VLBA. This variation in the maser intensity is more pronounced than observed before (Claussen et al. 2007).
Fig. 2. Channel velocity map (Jy beam$^{-1}$) of the SiO maser ($v = 1, J = 1 - 0$) emission for the epoch as indicated by the label in the last panel. The contour levels are at 5σ, 7σ, 9σ, and 11σ, where σ is the rms noise measured in the strongest channel of the image cube (Table 1). Position offsets are relative to the position of the strongest pixel in the channel that has the maximum peak flux (cyan cross mark).
Fig. 2. Continued.

We detected three maser features in total, where a “feature” refers to emission observed in contiguous velocity channels at nearly the same position. Channel maps
using the entire \( uv \) range are presented in Figure 2 for the strongest maser feature. Unlike Claussen et al. (2007), who did not resolve emission in the peak of the line, our new VLBA maps appear to show some resolution. Figure 3 shows the emission from the second strongest feature, which is detected at low S/N and in only four epochs at \( \approx 7 \) mas northeast of the strongest feature. This feature is blueshifted by \( \approx 0.9 \) km s\(^{-1} \) relative to the main feature. Last, a third feature is redshifted (\( V_{\text{LSR}} \approx 58 \) km s\(^{-1} \)) and detected only in the first and second epochs at \( \approx 1.5 \) mas eastward of the strongest feature (Figure 4). Figure 5 shows the spatial location of the three maser features.

4. Astrometry

In order to derive astrometric parameters for V838 Mon, we first selected two contiguous velocity channels with the strongest SiO emission (maser channels at 55.1 and 54.9 km s\(^{-1} \)). The emission in these channels is resolved in most epochs, so in order to minimize the effects of extended emission we imaged the data with a minimum \( uv \) length of 100 or 150 MA (the limit of 100 MA was chosen in the epochs where the maser emission is weak, since omitting the more of the data resulted in nondetections). We then fit a 2D Gaussian to the brightness distribution using the AIPS task JMFIT. The positions measured in the maps, derived with J0656–0323 as the reference source, are given in Table 2. Then, we simultaneously fit the positions of the two maser channels, solving for a single parallax (\( \varpi \)), but allowing for different proper motions (\( \mu_\alpha \cos \delta, \mu_\delta \)) and position offsets (\( \alpha_0, \delta_0 \)) at the reference epoch equal to the mean of the observed epochs. We should note that the B3V companion is between 28 and 250 au from the primary, which implies an orbital period in the range 40 to 1000 yr (assuming a circular orbit). Thus, we do not expect that the orbital motion has a measurable effect on the motion of the primary over the 1.4 years of our observations. Figure 6 shows the best fit for the resulting astrometric elements given in Table 3. Our fitting routine computes additional systematic errors to be added in quadrature to the statistical source position errors provided by JMFIT. These errors are estimated numerically so as to make the reduced \( \chi^2 \approx 1 \) for each coordinate. The resulting best fit parallax is

\[
\varpi = 0.166 \pm 0.060 \text{ mas},
\]

where we have multiplied the parallax uncertainty by \( \sqrt{2} \) to account for possible systematic errors, which would be fully correlated for the two maser channels. Fitting each spot separately gives similar results for all astrometric parameters, but with slightly larger uncertainties.

We note that the fractional parallax error is significantly large, thus, we should take particular care when estimating the distance and its uncertainty from the parallax. Since simply inverting the parallax yields a poor approximation of the distance, we used Bayesian inference. For a truncated uniform prior, an unnormalized posterior probability density function (PDF) given by (Bailer-Jones 2015) is as follows:

\[
P^*(r | \varpi, \sigma_\varpi) = \begin{cases} 
\frac{1}{r_\text{lim} \sqrt{2\pi\sigma_\varpi}} \exp \left[-\frac{1}{2\sigma_\varpi} (\varpi - \frac{r}{2})^2 \right], & \text{if } r < 0 \leq r_\text{lim} \\
0, & \text{otherwise.}
\end{cases}
\]

This astrometric-based posterior PDF for \( r_\text{lim} = 20 \) kpc is shown in the right panel of Figure 7.

Finally, we apply the parallax-based distance estimator of Reid et al. (2016, 2019) for sources associated with spiral arms in the Milky Way in order to derive a combined PDF. This estimator combines other distance information including spiral arm assignment (SA), kinematic distances based on radial velocity (KD), and two components of proper motion (PM(long) and PM(lat)):

\[
\text{Prob}(d) \propto \text{Prob}_{\text{SA}}(d) \times \text{Prob}_{\text{KD}}(d) \times \text{Prob}_{\text{PM(long)}}(d) \times \text{Prob}_{\text{PM(lat)}}(d).
\]

The left panel in Figure 7 shows the individual parameters of the parallax-based distance estimator, as well as the combined PDF. We have used \( V_{\text{LSR}} = 55 \pm 5 \) km s\(^{-1} \) and the average of the proper motions of the two maser spots, \( \mu_\alpha \cos \delta = -0.465 \pm 0.056 \text{ mas yr}^{-1} \) and \( \mu_\delta = 0.791 \pm 0.065 \text{ mas yr}^{-1} \). The source is most likely associated with the Outer spiral arm at a distance of 5.5 kpc (as previously suggested by Kamiński et al. 2011 and Quiroga-Nuñez et al. 2019).

For the second strongest spot, we were able to only estimate its proper motion using the positions fit to the brightness distribution at \( V_{\text{LSR}} \) of 54.2 km s\(^{-1} \) (listed in Table 3 and shown in Figure 5).

We have searched the Gaia DR2 catalog and found a star (2MASS J07040482-0350506) within a search radius of 1 arcsec of the SiO maser position. When propagating the Gaia position at J2015.5 to the VLBA observing epochs, we found that this source has a separation of only 2.4 mas from the VLBA position of the strongest maser. This star

Table 3. Astrometric parameters from VLBA

| Maser V_{\text{LSR}} (km s^{-1}) | \alpha_0 (0^\circ 0^\prime 0^\prime\prime) | \delta_0 (+0^\circ 0^\prime 0^\prime\prime) | \mu_\alpha \cos \delta (mas/yr) | \mu_\delta (mas/yr) | \varpi (mas) | D (kpc) |
|-----------------------------|---------------------|---------------------|---------------------|---------------------|-------------|-------|

| 54.2                        | 4.821862(2)         | 50.6293(1)          | -0.553               | 0.339               | 0.167       | -     |

Notes. Numbers in parenthesis give position errors in units of the last significant digits. (a) Distance inferred from the inversion of the parallax.
has a DR2 parallax of \(-0.001 \pm 0.105\) mas. For comparison with our VLBA distance PDF, we have constructed the Gaia DR2 distance PDF using a truncated uniform prior as shown in the right panel of Figure 7. Similarly, we show the posterior PDF that corresponds to the light-echo distance measurement by Sparks et al. (2008). These PDFs can be combined with the distance PDF given by equation (3) to provide a more robust distance estimate than either alone. The combination of equation (3) with the VLBA astrometric-based PDF yields \(d = 5.5 \pm 0.6\) kpc, while the combination of all PDFs yields \(d = 5.9 \pm 0.4\) kpc, where the distance and its uncertainty have been obtained by fitting a Gaussian model to the combined PDF and estimating its peak probability density, center, and width. Table 4 summarizes all the distance results discussed above. We include the Gaia result for completeness even though it is highly uncertain and contributes little to the final distance estimate.

### Table 4. Parallax measurements

Our study provides an example that Gaia DR2 parallaxes for distant supergiants should be treated with caution.

As described in the introduction, V838 Mon is a binary system consisting of a cool giant (the eruptive component) and the B3V companion. An effective temperature of $T_{\text{eff}} \sim 2000 - 3000$ K was measured for the merged star from optical and IR spectroscopy in 2008-2009 (Tylenda et al. 2011; Loehman et al. 2015). The B3V companion has been attenuated by the V838 Mon outburst ejecta (Goranskij et al. 2008), which explains why it is not detected by Gaia. It is important to note that the astrometric parameters measured by Gaia toward V838 Mon may be affected by extinction from the dusty region around V838 Mon. The DR2 quality factors of the solution suggest that the source is astrometrically well-behaved; however, the relative errors on the astrometric parameters are quite large and the parallax is negative. The Gaia proper motion measurement strongly disagrees with that measured by the VLBA, as well as the Gaia proper motions of other stars in the V838 Mon cluster (see Section 5.1).

5. Discussion

5.1. The cluster of V838 Mon

Gaia DR2 parallaxes and proper motions of the three stars that are considered to be members of the open cluster of V838 Mon (Afsar & Bond 2007), although highly uncertain, are similar to those derived by our VLBA measurements. These stars are spectroscopically identified as B-type main-sequence stars. Their individual parallaxes are between 0.17 and 0.24 mas and have a weighted-mean parallax of $0.18 \pm 0.10$ mas, after correcting for a Gaia DR2 parallax zero-point shift of $-0.029$ mas\(^1\), which agrees with our VLBA parallax of V838 Mon. Their mean proper motion is $-0.49 \pm 0.11$ and $0.54 \pm 0.11$ mas yr\(^{-1}\) in the easterly and northerly directions, respectively\(^2\). We note that the mean proper motion in declination of the SiO masers is consistent with the mean cluster motion within $\sim 2\sigma$ uncertainty, whereas the agreement in the parallaxes and RA proper motion is even better.

\(^1\) We note that larger values for the zero-point offset have been reported in the literature (e.g., $-0.08$ mas by Stassun & Torres 2018). Here and throughout the paper we use the value of $-0.029$ mas derived by the Gaia-DR2 team (Lindegren et al. 2018).

\(^2\) We have added quadratically systematic errors of 0.1 mas for parallax and 0.1 mas yr\(^{-1}\) for proper motions (Luri et al. 2018).
We also note that the Gaia DR2 effective temperatures for the three B-type stars with known visual spectra (Afsar & Bond 2007) appear significantly low, most likely owing to a high extinction ($E_{B-V} \approx 0.8$) toward the cluster not taken into account in the Gaia catalog (Andrae et al. 2018). This puts into question the Gaia effective temperature listed at 3342K for V838 Mon itself, although this value is close, within 3$\sigma$, to that expected (Loebman et al. 2015).

We looked for other potential members of the cluster by searching for sources with similar parallaxes and proper motions as V838 Mon and the three cluster members. Within a radius of 2$'$3 of V838 Mon, we find only one candidate in the Gaia DR2 catalog, star 3107789583219504000, which is 6$''$ east of V838 Mon. The Gaia parallax for this star (0.16$\pm$0.14 mas) is highly uncertain, but consistent with a distance beyond 3 kpc. Its location and proper motion are shown in Fig. 8. Its angular distance from V838 Mon is the smallest among the four stars in the cluster. It is also fainter than the three B-type stars which may be indicative of a spectral type later than B6. In the maps of Wisniewski et al. (2003), this star is numbered 4 and has a slightly smaller interstellar linear polarization degree and a slightly different orientation of the polarization plane than the three confirmed cluster members. However, given the patchy morphology of the echo material and the patchy dust distribution toward the V838 Mon cluster (Sparks et al. 2008; Tylenda & Kamiński 2012), the difference does not exclude that we have identified a genuine fourth member of the cluster (not counting the stars in V838 Mon itself).

Given that the considered merger of V838 Mon took place in a triple or higher system, it is worth considering whether any star (including V838 Mon itself) could have been “kicked out” (or dynamically ejected) off the system (see e.g., Perets & Šubr 2012). This would probably be manifested by proper motions significantly different than that of the cluster. This is not observed for V838 Mon at the current accuracy of the VLBA measurements. Indeed, after subtracting the mean proper motion of the cluster from the VLBA proper motions, we obtain that V838 Mon has a transverse velocity relative to the cluster of 7$\pm$5 km s$^{-1}$. The radial component is unknown. This low velocity implies a small displacement of V838 Mon as a result of the “kick”. If we assume that the ejection took place in 2002, we obtain a displacement of only 4$\pm$2 mas or 25$\pm$12 au. The low velocity is inconsistent with the ejection scenario. However, constraints on the motion of the now dust-embedded physical companion of V838 Mon are very poor (Kamiński et al. 2009), thus we cannot completely rule out that this component has been dynamically ejected.

5.2. Location of the stellar photosphere in VLBA maps

Optical observations, the photospheric size (Chesneau et al. 2014), and the presence of an SiO maser make V838 Mon very similar to red supergiants with highest mass-loss rates. SiO masers observed in Asymptotic Giant Branch (AGB)
stars, and Mira stars in particular, often take the form of a ring surrounding the star. In such cases, it is relatively straightforward to identify the location of the stellar photosphere, even if it is not directly detected in the same observations (see, e.g., Cotton et al. 2008). This task is more difficult for red supergiants whose mass loss may be very inhomogeneous and the distribution of SiO maser spots may be very erratic. VY CMa is the best known example of such a complexity (Zhang et al. 2012). In our maps of the maser emission in V838 Mon we probably detect only the three brightest SiO maser spots. Assuming that their distribution is as complex as in red supergiants, we are unable to identify the location of the stellar photosphere in the radio maps. Given that V838 Mon is an unresolved binary for Gaia, we are also unable to associate the Gaia position to the V838 Mon merger product or the companion. The stellar remnant of the component of V838 Mon that erupted in 2002 remains the brightest radiation source of the system. Part of its energy is generated by continuing contraction and thus it has a higher bolometric luminosity than the B3V companion. The stellar radiation heats the surrounding dust expelled during the eruption producing emission at millimeter wavelengths. The emission is brightest closest to the contracting luminous star. Thus, we can take the position of the millimeter-wave continuum peak as the stellar (photosphere) position. We see in Figure 5 that this peak is located between the two brightest maser spots (within the modest accuracy of the ALMA position measurements; \( \approx \pm 3 \) mas).

Chesneau et al. (2014) observed the mid-IR (dust) emission around V838 Mon with the Very Large Telescope Interferometer array and derived a major axis size of 25 mas at 8 \( \mu \)m and 70 mas at 13 \( \mu \)m (147 and 412 au at 5.9 kpc, respectively). The dust emission is flatter at 13 \( \mu \)m and has a position angle of about \(-10^\circ\). This dusty structure, interpreted as a disk, is believed to have formed after the outburst in 2002 as a result of the merger event. For the central star, Chesneau et al. (2014) derived a diameter of 1.15 \( \pm \) 0.20 mas (\( \approx \)6.8 au at 5.9 kpc). The SiO maser spots are located within the extended dusty structure around V838 Mon at \( \approx \)5 mas (\( \approx \)30 au) from the stellar position (as measured in the ALMA continuum map), that is, at \( \approx \)9 stellar radii but within the dusty structure identified by Chesneau et al. (2014). This supports the idea that V838 Mon and AGB stars resemble each other, since in AGBs the SiO masers are found in the immediate vicinity of the stellar photosphere (Cotton et al. 2008).

5.3. Extended emission detected with ALMA

The velocity-integrated intensity map of the SiO thermal emission detected by ALMA is shown in Figure 9. This corresponds to the SiO \( v = 0, J = 5 - 4 \) transition at 217 GHz, which shows a very broad profile with a FWHM of 225 km s\(^{-1}\) for the entire emission region. The emission has an extended structure with a beam-deconvolved size of 148 \( \times \) 125 \( (\pm 30) \) mas. The major axis of this structure is aligned at a position angle of 61 \( \pm \) 7\(^\circ\). Continuum emission contours at 225 GHz are overlaid in Figure 9. The continuum has a peak flux density of 0.43 mJy beam\(^{-1}\) and an elongated morphology in a direction almost perpendicular to the major axis of the SiO thermal emission. The extent of the continuum structure is about 150 mas. Gaussian fits yield the continuum peak at RA=07:04:04.821535 \( (\pm 0.17 \) mas) and Dec=--03:50:50.629426 \( (\pm 0.18 \) mas), and the extended SiO emission peaks at RA=07:04:08.822
6. Conclusions

Multiepoch VLBA observations of the SiO $v=1$, $J=1-0$ maser transitions at 43 GHz have been obtained toward the red transient V838 Mon. Three maser spots from the $v=1$ line were firmly detected, while the $v=2$ line was tentatively detected in only one epoch. We modeled the motion of maser spots which were detected in two contiguous channels at 6 epochs to fit the astrometric parameters of the source. The resulting best-fit parallax is $0.166 \pm 0.060$ mas. Using Bayesian inference, we combined our VLBA parallax with other distance information to arrive at an improved distance of $5.9 \pm 0.4$ kpc. Quiroga-Nuñez et al. (2019) and Reid et al. (2019) considered whether V838 Mon is in the Perseus arm, the Outer arm, or the interarm region, and favored the Outer arm. The improved distance of $5.9 \pm 0.4$ kpc indicates that it is further than 5 kpc which favors it being in the Outer arm.

Proper motions of field stars in the vicinity of V838 Mon were taken from Gaia-DR2. The mean proper motion of the three known members of the V838 Mon open cluster is consistent within 2\sigma with the VLBA proper motions, confirming its membership. A possible new member of the cluster was also identified.

Finally, observations taken with ALMA of SiO thermal emission at 217 GHz revealed an extended outflow with a size of $148 \times 125$ mas ($870 \times 740$ au). The major axis of this structure is perpendicular to 225 GHz continuum emission, which shows an elongated and complex structure.
