Abstract

The spectral observations and analysis for the W80 region are presented by using the data of Medium-Resolution Spectroscopic Survey of Nebulae (MRS-N) with the Large Sky Area Multi-Object Fiber Spectroscopic Telescope (LAMOST). A total of 2982 high-quality nebular spectra have been obtained in the 20 degree field of view which covers the W80 complex, and the largest sample of spectral data has been established for the first time. The relative intensities, radial velocities (RVs), and full widths at half maximum (FWHMs) are measured with the high spectral resolution of LAMOST MRS-N, for Hα λ6563 Å, [N II] λλ6548 Å, 6584 Å, and [S II] λλ6716 Å, 6731 Å emission lines. In the field of view of the whole W80 region, the strongest line emissions are found to be consistent with the bright nebulae NGC 7000, IC 5070, and LBN 391, and weak line emissions also exist in the Middle Region, where no bright nebulae are detected by the wide-band optical observations. The large-scale spectral observations of the W80 region reveal the systematic spatial variations of RVs and FWHMs, and several unique structural features. A “curved feature” to the east of NGC 7000, and a “jet feature” to the west of LBN 391 are detected to be showing larger RVs. A “wider FWHM region” is identified in the eastern part of NGC 7000. The variations of [S II]/Hα ratios display a gradient from southwest to northeast in the NGC 7000 region, and manifest a ring shape around the “W80 bubble” ionized by an O-type star in L935. Further spectral and multi-band observations are guaranteed to investigate in detail the structural features.

Key words: surveys – (ISM:) HII regions – ISM: molecules – ISM: bubbles – methods: statistical

1. Introduction

Ionized hydrogen is generated when the ultraviolet light emitted by a massive star ionizes the surrounding gas. Previous work has shown that about 14% to 22% of the new generation of massive young stars are produced by the interaction of ionized hydrogen regions with surrounding molecular clouds (Hausen et al. 2002). The study of ionized hydrogen is of great significance to our understanding of the interactions between massive stars and the surrounding molecular clouds.

The W80 complex is a classical H II region located in the Cygnus region. The nebular complex contains the North America Nebula (NGC 7000) and the Pelican Nebula (IC 5070) (hereafter NAP nebulae), and a large dust cloud L935 (Westerhout 1958; Cersosimo et al. 2007). There is an O-type star, 2MASS J20555125 + 4352246, embedded in the region as the ionizing source (Comerón and Pasquali 2005). The central ionizing star is surrounded by a bubble with a radius of 20 pc, and the distance of the NAP region is about 800 pc (Zucker et al. 2020). The mass of the NAP nebulae is measured to be from \(3 \times 10^4 \ M_\odot\) to \(5 \times 10^4 \ M_\odot\) (Feldt & Wendker 1993; Bully & Scoville 1980). T-Tauri star associations (Herbig 1958) and a large number of outflow activities have been observed in the NAP nebulae, such as Herbig-Haro objects (HH objects), molecular hydrogen emission-line objects (MHOs), and H2O masers (Bally & Reipurth 2003; Armont et al. 2011). Molecular gas spectra, like NH3, 12CO, 13CO, C18O, and HCO+, have been observed toward the L935 dust cloud (Zhang et al. 2014). Using the Spitzer MIPS data, Guieu et al. (2009) identified more than 2000 candidates of young stellar objects (YSOs) inside the NAP nebulae. Thus the W80 complex is an ideal target to study the interactions of ionized hydrogen regions with molecular clouds in the process of star formation and early evolution.

Figure 1 displays the Digitized Sky Survey (DSS) optical image of the NAP nebulae, with the positions of the ionizing source, YSOs, and T-Tauri star associations marked. The positions of three stellar clusters, N6996, N6997, and Col428...
Collinder 1931, are also marked. The outer contours of the bright nebulae are superimposed on the optical image for a better view. For the large-scale W80 region with low nebular brightness, only a few optical spectral observations have been made. Even in these observations, the amount of data is very limited. Pedlar & Matthews (1973) obtained the Hα emission line observations of the W80 complex, and presented the average radial velocities (RVs) around \(-16\) km s\(^{-1}\) of IC 5070, NGC 7000, and W80 complex first. Fountain et al. (1983) made spectral observations of Hα emission lines in 1983 to about 100 positions of the W80 region with a multi-slit Echelon spectrograph. Haffner et al. (2003) observed only five positions with the Wisconsin H-alpha Mapper (WHAM) in 2003. The most recent spectral observations were made by Aksaker (2013), and 26 spectra were obtained with the Dual Etalon Fabry–Perot Optical Spectrometer (DEFPOS). The data mentioned above contributed greatly to our understanding of the physical conditions in the W80 region.

Nowadays, the Large Sky Area Multi-Object Fiber Spectroscopic Telescope (LAMOST) Medium-Resolution Spectroscopic Survey of Nebulae (MRS-N) project (Su & Cui 2004; Cui et al. 2012; Zhao et al. 2012; Wu et al. 2021) provides us with a great opportunity to make spectral observations of the W80 region. With multiple fibers and the 5 degree wide field of view (FoV) of LAMOST, almost 4000 spectra can be obtained by one exposure. The closest spacing between optical fibers is about 2′. In this study of the W80 region, the 20 square degree FoV covers not only the W80 complex but also the western region of the bright nebula LBN 391 (LBN 087.23-03.80). LBN 391 is also known as the Sharpless 2–119 Region (SH 2-119) (Dubout-Crillon 1976). In this work, we refer to this region as the LBN 391 nebula. Based on the large spatial coverage of LAMOST, we perform an almost complete spectral investigation for the W80 region.

The electrons in nebular gas are excited or ionized by the ultraviolet radiation of hot stars. The recombination or de-excitation of electrons produces Hα line (\(\sim6563\) Å) emission.
The forbidden lines are usually detected in a low-temperature and low-density astrophysical environment. The [N II] at 6548 and 6584 Å, [S II] at 6716 and 6731 Å, [O II] at 3727 Å, and [O III] at 4959 and 5007 Å are several common forbidden lines (Petrie 1952). By optical spectra, different emission lines can provide a very useful tool to identify the contributions of different radiation mechanisms such as photoionization and shock excitation.

This paper is organized as follows. The observational data reduction of the W80 region is described in Section 2. The observational results, including the relative intensity, RV, full width at half maximum (FWHM), and electron density are presented in Section 3. In Section 4, some interesting features are discussed. Section 5 gives a summary.

2. Data Reduction

2.1. Data Selection

The focal plane of LAMOST is circular, and has 4000 fibers evenly distributed within a diameter of 5°, and each fiber can move within a radius of 2′. The unique design enables LAMOST to obtain 4000 spectra by one exposure. By 2017, LAMOST had completed a five-year regular sky survey with low spectral resolution (R ~ 1800). In October 2018, the MRS-N was officially initiated with higher spectral resolution (R ~ 7500, Wu et al. 2021). The MRS-N survey includes both blue band (from 4950 to 5350 Å) and red band (from 6300 to 6800 Å).

The MRS-N covers about 1,700 square degrees in the range of $40^\circ < l < 215^\circ$ and $-5^\circ < b < 5^\circ$ along the Galactic plane. Some bright stars and a large number of Galactic nebulae are set to be observed. For detailed information about the MRS-N, refer to Wu et al. (2021), Ren et al. (2021), Zhang et al. (2021), and Wu et al. (2021b). Wu et al. (2021) presented the survey plan of LAMOST MRS-N and the detailed scientific goals. Ren et al. (2021) reported the RV calibrations toward the LAMOST MRS-N. Zhang et al. (2021) proposed the method for eliminating geocoronal Hα emissions from the LAMOST MRS-N spectra. Wu et al. (2021b) described in detail the MRS-N pipeline with each data processing phase. In this work, we have made data reduction following the same pipeline.

The W80 region was observed on 2020 November 8, with the exposure time of 3 x 900 s. After the standard data reduction for the MRS-N spectra using the pipeline, the invalid data with a signal-to-noise ratio (S/N) of 999 were deleted first, and about 3800 spectra were obtained. In order to ensure that all the spectra are nebular, the stellar spectra were rejected. Then Gaussian fitting was applied to all the emission lines, and only the spectra with high S/N (S/N > 10) for all the Hα, [N II], and [S II] emission lines were selected for reliable analysis accuracy. We finally obtained a total of 2982 spectra for the W80 region.

Figure 2 presents one typical spectrum as an example of the 2982 spectra, together with the Gaussian fitting (the smallest variance $\chi^2$) for the Hα, [N II], and [S II] emission lines. The spectral fitting provides us with measurements of the RVs, FWHMs, and relative intensities of the Hα, [N II], and [S II] emission lines. For the Hα line with an S/N ratio of 146, the Gaussian fitting gives an RV uncertainty of 0.1 km s$^{-1}$ and FWHM$_{obs}$ uncertainty of 0.4 km s$^{-1}$, and for the [N II] line with an S/N ratio of 89, RV uncertainty of 0.2 km s$^{-1}$ and FWHM$_{obs}$ uncertainty of 0.5 km s$^{-1}$; the [S II] line has a relatively poor S/N ratio of 71, and its RV uncertainty is 0.3 km s$^{-1}$ and FWHM$_{obs}$ uncertainty of 0.8 km s$^{-1}$. There was no further flux calibration made, and we simply performed the analysis of the intensities relative to those of the $\lambda6554$ skyline.

Figure 3 presents the spatial distribution of the selected 2982 nebular spectra of Hα emission lines, with all the points satisfying S/N > 10. We note that the spectral data points are more evenly distributed over the W80 region, and the data are much more than the previous spectral observations. The areas of bright nebulae NGC 7000, IC 5070 and LBN 391 have higher S/N ratios. The two magenta dashed lines divide the LBN 391 nebula region, the W80 complex, and the Middle Region.

Figure 4 plots the RV uncertainties of the three emission lines with the S/N ratios for the selected 2982 spectra. There are 99.8% RV uncertainties less than 1.0 km s$^{-1}$ for the Hα lines, 99.3% RV uncertainties less than 1.5 km s$^{-1}$ for the [N II] lines, and for the [S II] lines, 99.3% RV uncertainties less than 2.0 km s$^{-1}$. It is reasonable for data analysis to take the RV uncertainties less than 2 km s$^{-1}$ for the three emission lines.

2.2. Calibration of FWHM

The broadening of emission lines is generally caused by a natural broadening of particles, elastic collisions between particles, energy disturbances, and thermal motion of radiating particles. Besides these physical broadenings, instrumental broadening is another important factor. We need to subtract the instrumental broadening effect from the observed FWHMs.

For spectral observations, the standard arc lines and skylines are commonly used to estimate the instrumental broadening. Zhang et al. (2021) separately compared the line dispersion of the arc lines with the $\lambda6554$ skyline of LAMOST MRS-N spectra, and found that the line dispersion of $\lambda6554$ is identical with that of the arc line. Because the values of line dispersion are different for different fibers, in this work, the instrumental broadening of each spectrum has been removed with its own $\lambda6554$ skyline.

The FWHM correction has been made according to Equation (1) (Reynolds et al. 1977), and the FWHM uncertainties are calculated by using the error propagation equation.

\[ \text{FWHM}_{\text{obs}}^2 = \text{FWHM}_{\text{real}}^2 + \text{FWHM}_{\text{inst}}^2. \]  

(1)

where FWHM$_{obs}$ is the observed FWHMs, FWHM$_{inst}$ is the instrumental FWHMs, and FWHM$_{real}$ is the corrected FWHMs,
with the unit of FWHM being km s$^{-1}$. With no more specific notes, all the FWHMs in this work represent the corrected FWHMs ($\text{FWHM}_{\text{real}}$, $\sigma_{\text{FWHM}}$$_{\text{obs}}$ is the uncertainty of FWHM$_{\text{obs}}$ and $\sigma_{\text{FWHM}}$$_{\text{inst}}$ is the uncertainty of FWHM$_{\text{inst}}$). Because the λ6554 skyline is a little far from the [S II] $\lambda\lambda$ 6716, 6731 Å lines, which could induce larger uncertainties, we present the FWHM results and related analysis only for the Hα and [N II] emission lines.

Further criteria have been set to control the analysis accuracy to avoid contamination by the spectra with larger FWHM uncertainties. First, we selected the spectra such that the FWHM$_{\text{obs}}$ values were greater than the FWHM$_{\text{inst}}$, that is, $\text{FWHM}_{\text{obs}} > \text{FWHM}_{\text{inst}} + \sigma_{\text{FWHM}}$. Here, $\sigma_{\text{FWHM}}$ is the uncertainty of FWHM$_{\text{obs}}$. 95.7% $\sigma_{\text{FWHM}}$ of Hα lines are less than 1.5 km s$^{-1}$, and 95.4% $\sigma_{\text{FWHM}}$ of [N II] lines are less than 2.5 km s$^{-1}$; and $\sigma_{\text{FWHM}}$ is the uncertainty of FWHM$_{\text{inst}}$. 96.6% $\sigma_{\text{FWHM}}$ are less than 2 km s$^{-1}$. Then, we selected the spectra satisfying $\text{FWHM}_{\text{real}} > 3 \sigma_{\text{FWHM}}$, where $\sigma_{\text{FWHM}}$ is the uncertainty of FWHM$_{\text{real}}$. We finally obtained 1903 spectra for FWHM analysis in the whole region, for both the Hα and [N II] emission lines. For the 1903 spectra, we find that 99.1% FWHM uncertainties of Hα lines are less than 4 km s$^{-1}$, and 94.3% FWHM uncertainties of [N II] lines are less than 5 km s$^{-1}$. It is reasonable for us to take the FWHM uncertainty of 5 km s$^{-1}$ for further analysis.

3. Results

The LAMOST MRS-N project provides us with an effective method to understand the whole nebula region in detail. As shown in Figure 3, the 2982 spectra we obtained for the Hα, [N II], and [S II] emission lines all have high S/N ratios and...
reasonable spatial distribution, confirming the existence of emission lines in the whole region.

The relative intensities, RVs, and FWHMs of the Hα, [N II], and [S II] emission lines are measured for the W80 region. To make the presentation clear, the following sections begin with the spatial distribution, followed by the histogram analysis of the W80 complex. The electron density is calculated with the intensity ratios of double [S II] emission lines.

3.1. The Relative Intensity

The intensities discussed in this work are the relative intensities corrected by the simultaneously observed λ6554 skylines of each fiber, for all the Hα, [N II], and [S II] emission lines.

Figure 5 features the spatial distribution of relative intensities, with colors ranging from blue to red indicating weak to strong intensity. The western part of the FoV is the W80 complex, which contains the NGC 7000, L935 and IC 5070 regions. The eastern part of the FoV is the bright nebula LBN 391. The area between the LBN 391 nebula and the W80 complex in this work is called the Middle Region.

It is worth noting that Hα emission in the NGC 7000 region is mainly concentrated in the central part, while the stronger [N II] and [S II] emissions are spread at the northeastern edge. This feature is particularly evident for the [S II] emissions.

Figure 6 displays histograms of relative intensities for the three regions. The left panel is for NGC 7000, the middle is IC 5070 and the right is the W80 complex. The intensities of IC 5070 are the weakest in the three regions, and a peak in Hα emission appears in the range of 30 to 40. The intensities of NGC 7000 and the W80 complex are basically consistent, and the maximum intensity values of Hα, [N II] and [S II] emission are 100, 40 and 20, respectively.

Figure 7 presents histograms of relative intensities for three emission lines. The left panel is the intensity distribution of Hα, the middle is [N II] and the right is [S II] emission lines.

The Hα emissions have the strongest intensity and [S II] emissions are the weakest.

3.2. The Radial Velocity

All the RVs presented in this work are corrected to be heliocentric. A positive RV value means the target is moving away from us, while a negative RV means moving toward us.

The RV spatial distributions of all spectra are presented in Figure 8. Figure 8(a1) shows the RV distributions of the Hα emission lines. The bright nebulae within the W80 complex have a velocity range from −25 to −15 km s$^{-1}$, and the velocity range of −10 to 0 km s$^{-1}$ can be seen in the Middle Region, in which some velocity components of −5 to +5 km s$^{-1}$ are visible in the northern part. The LBN 391 nebula has obviously different velocity regions; its northern region mainly has velocities between −10 to 0 km s$^{-1}$, while the southern region shows velocity values from −25 to −15 km s$^{-1}$, indicating that the two regions must have different velocity components.

Figure 8(a2) further shows the interpolated map of RVs for the Hα emission line, in order to reveal the RV features in each region more clearly. For the W80 complex, the RVs of NGC 7000 and IC 5070 are merged together, not being separated as in the intensity map, indicating that the two nebulae are moving toward us at a uniform velocity. Wendker (1968), Wendker et al. (1983) pointed out the NAP nebulae are all part of the same extended H II region, and Bally & Scoville (1980) deduced from CO observations that the NAP complex may be a huge molecular cloud being destroyed by early-type stars.

It is worth noting that there is a high-speed “curved feature” extending to the east from the bright nebula NGC 7000, and the RVs of this feature are concentrated at −30 to −25 km s$^{-1}$ (see Figure 8(a2), red arrow line). This feature extends further to the northeast beyond NGC 7000. To the LBN 391 nebula, there is also a “jet feature” extending along the east–west direction, which is also beyond the intensity scope of the LBN 391.
Figure 5. The spatial distributions of the relative intensities of (a) $\text{H}\alpha$, (b) $[\text{N}\ II]$ and (c) $[\text{S}\ II]$ emission lines. The magenta dashed lines in (a) indicate the LBN 391 nebula and the W80 complex, and the Middle Region composes the region between them. The color bar shows the log values of relative intensities.

Figure 6. The histograms of relative intensities for NGC 7000 (left panel), IC 5070 (middle panel), and the W80 complex (right panel).
nubula. Considering the 2 km s\(^{-1}\) uncertainty of the RV measurements and relatively shaped structures, we believe these large RV features are real. The similar RV values of \(-30\) to \(-25\) km s\(^{-1}\) can be also seen associated with the bright nebula IC 5070 and dark cloud L935.

In order to study the RV distributions, we present two sets of histograms. Figure 9 features the histograms for the three regions; the left panel is NGC 7000, the middle is IC 5070 and the right is the W80 complex. Among the three regions, IC 5070 has the largest RV values; the peak RV of H\(_{\alpha}\) emission lines is at \(-20.1\) km s\(^{-1}\), the [N\(_{\text{II}}\)] emission lines at \(-19.9\) km s\(^{-1}\), and the [S\(_{\text{II}}\)] emission lines at \(-16.1\) km s\(^{-1}\).

The range of the RV distribution of NGC 7000 is basically similar to that of the W80 complex, and the RVs of H\(_{\alpha}\) emission lines are concentrated at \(-16.0\) km s\(^{-1}\), the [N\(_{\text{II}}\)] emission lines at \(-16.0\) km s\(^{-1}\), and the [S\(_{\text{II}}\)] emission lines at \(-13.9\) km s\(^{-1}\). We have noticed the fact that our FoV (see Figure 3) does not fully cover the entire IC 5070 nebula.

Compared to the RVs of the H\(_{\alpha}\), [N\(_{\text{II}}\)] emission lines, the RVs of the [S\(_{\text{II}}\)] emission lines display inconsistencies, and there is about a 5 km s\(^{-1}\) difference between the RV peaks. We have in fact checked the RV uncertainties for those bright nebular regions, in which the RV uncertainties of the [S\(_{\text{II}}\)] emission lines are all distributed below 0.5 km s\(^{-1}\). So, the RV inconsistencies are real and may indicate different components detected along the line of sight. Kewley et al. (2019) pointed out that different ionization lines of different species probe different zones of a nebula. The [S\(_{\text{II}}\)] emission lines may trace the very outer edge of the nebula.

Figure 10 presents three histograms of RVs for three emission lines; the left panel is H\(_{\alpha}\), the middle is [N\(_{\text{II}}\)] and the right is the [S\(_{\text{II}}\)] emission lines. It can be seen that the [S\(_{\text{II}}\)] emission lines have the lowest RV values in NGC 7000, IC 5070, and the W80 complex, and their RVs peak at \(-13.9\), \(-16.9\), and \(-14.0\) km s\(^{-1}\) respectively. The RV distributions of H\(_{\alpha}\) emission lines peak at \(-15.6\), \(-20.2\), and \(-16.4\) km s\(^{-1}\), and the [N\(_{\text{II}}\)] emission lines peak at \(-15.6\), \(-19.9\), and \(-16.0\) km s\(^{-1}\), respectively. The RV distributions of the H\(_{\alpha}\) emission lines and the [N\(_{\text{II}}\)] emission lines are consistent.

### 3.3. The FWHM

The FWHMs can provide us with information such as temperature, gas pressure, and star rotational velocity (Michelson 1895). The FWHMs allow us to learn more about nebular properties. Figure 11 depicts the spatial distributions of FWHMs. Figure 11(a) and (b) is the full FoV distributions for the W80 region of H\(_{\alpha}\) and [N\(_{\text{II}}\)], respectively. Figure 11(c) and (d) shows a close view for the NGC 7000 region. The FWHMs in the regions covered by bright nebulae are narrow, mainly below 20 km s\(^{-1}\). In the Middle Region, which is not covered by bright nebulae, we have discovered that the FWHMs are generally wider and the values over 30 km s\(^{-1}\).

In particular, Figure 11(a) shows the blue dashed ovals in the Middle Region have the widest FWHMs, reaching 40 \~ 60 km s\(^{-1}\). We have labeled “M1” to “M4” denoting the blue dashed ovals from north to south respectively in Figure 11(a), in which the position and direction of “M3” are consistent with the larger RV “jet feature”.

In addition, we noticed a “wider FWHM region” in the eastern part of bright nebula NGC 7000 (see the orange circle in Figure 11), signified by both H\(_{\alpha}\) and [N\(_{\text{II}}\)] emission lines. The region has higher FWHM values than the other parts in NGC 7000. Figure 11(c) and (d) displays the close view for only the NGC 7000 region, and is clearer with only the 529 data points associated. This “wider FWHM region” in fact
coincides with the location of the Col428 cluster, and we discuss more about the association in Section 4.3.

We present two sets of histograms to investigate the FWHM distributions. Figure 12 shows two FWHM histograms for Hα and [N II] emission lines; the left panel is Hα and the right is the [N II] emission lines. The FWHMs of [N II] for NGC 7000, IC 5070, and the W80 complex are 18.4 km s\(^{-1}\), 15.8 km s\(^{-1}\), and 18.1 km s\(^{-1}\) respectively. The FWHMs of Hα lines are distributed in a range of 20 ~ 40 km s\(^{-1}\), and FWHMs of [N II] lines in a range of 10 ~ 30 km s\(^{-1}\); the FWHMs of Hα are about 10 km s\(^{-1}\) larger than those of [N II]. We may understand the differences for nitrogen which is heavier than hydrogen. The histograms for the three regions are displayed in Figure 13; the left panel is NGC 7000, the middle panel is IC 5070, and the right panel is the W80 complex. The FWHMs of the IC 5070 region are the narrowest, with a peak for Hα emission lines at 21.9 km s\(^{-1}\), and a peak for [N II] emission lines at 15.8 km s\(^{-1}\). In the NGC 7000 and W80 complex, the FWHM distributions of the Hα and [N II] emission lines are nearly identical, with peaks at 26 km s\(^{-1}\) and 18 km s\(^{-1}\), respectively.

3.4. The Electron Density (n_e)

The electron density \(n_e\) can be calculated using a pair of nearly metastable lines. There is seldom a collision between ions and electrons in thin media, therefore the line ratio is exclusively determined by the Einstein coefficient. Saraph & Seaton (1970) used line ratios as an indicator for density, to calculate electron densities in planetary nebulae. Danks (1970) relied on the [S II] line or [O II] line as a parameter to calculate the electron densities in H II regions. We employed the updated formula (see Equation (2) and (3)) proposed by Proxauf et al. (2014) to calculate the electron densities by utilizing [S II] \(\lambda\)
6716 Å, 6731 Å intensity ratios.

\[ R = \frac{I_{6716}}{I_{6732}} \]  
\[ \log(n_e) = 0.0543 \tan(-3.0553R + 2.8506) + 6.98 - 10.6905R + 9.9186R^2 - 3.5442R^3, \]  

where \( I_{6716} \) and \( I_{6732} \) are the intensities of \( \lambda 6716 \) Å and \( \lambda 6732 \) Å lines respectively, and \( R \) is the ratio. With the electron temperature of 10000 K and the constraint of \( R < 1.42 \) (Proxauf et al. 2014), we obtain an average \( n_e \) of 29.7 cm\(^{-3}\) in NGC 7000 with 121 spectral points, and 40.0 cm\(^{-3}\) in IC 5070 with 22 data points. For the whole W80 complex, the average \( n_e \) is estimated to be 43.2 cm\(^{-3}\), with 171 spectral points. Kewley et al. (2019) obtained the electron densities of ionized nebulae in a range of 40–50,000 cm\(^{-3}\), with a new self-consistent [S II] doublet model. The electron densities of the W80 complex could be around lower values to be probed by the [S II] doublet.

4. Discussion

4.1. Emission Line Measurements in the W80 Region

The large FoV of LAMOST observations provides a powerful tool to reveal large-scale variations and unique
structures in nebulae. This section summarizes the spectral observations targeting the W80 region with statistics for each region and some structural features. The average values of RVs, relative intensities, and FWHMs for each corresponding region are presented in Table 1.

For the W80 region on the whole, the bright nebulae in NGC 7000, IC 5070 and LBN935 systematically possess larger RV values than the Middle Region; the mean RV of Hα emission lines in the W80 complex is $-16.7$ km s$^{-1}$, and $-11.2$ km s$^{-1}$ in the Middle Region. Considering the large scale of detection, we speculate that the systematical difference of the RVs could indicate an overall property of the local molecular clouds; in fact, the filamentary molecular clouds in this region are just distributed along the north-south direction (Zhang et al. 2014; Kong et al. 2021).

The overall spatial distribution of FWHMs also shows the bright nebular regions have narrower FWHMs than the Middle Region; the mean FWHM of Hα lines in the W80 complex is 26.2, and 35.8 km s$^{-1}$ in the Middle Region. For the bright nebulae the emission lines are observing a relatively short physical scale of the H II regions, while the weak line emissions in the Middle Region may indicate optical thinness and so longer distances along the line of sight. More velocity components along the long path could easily lead to relatively larger FWHMs.

As for different emission lines, the RVs of the Hα emission lines are basically the same as those of the [N II] emission lines and slightly larger than those of the [S II] emission lines. The mean RVs of the Hα and [N II] emission lines for the W80 complex are both about $-16$ and $-14.2$ km s$^{-1}$ of the [S II] emission lines respectively. The FWHMs of Hα emission lines

---

**Figure 11.** The spatial distributions of FWHMs of (a) Hα and (b) [N II] emission lines, and (c) (d) the close view for the NGC 7000 region. The orange circle indicates the so called “wider FWHM region”, and the four dashed ovals mark the widest FWHM areas. The color bar indicates the values of FWHMs.
are generally wider than the [N II] emission lines. The FWHMs of the two emission lines for the W80 complex are 26.2 and 17.8 km s$^{-1}$, respectively.

In NGC 7000, the “curved feature” shows an RV value about 2 km s$^{-1}$ larger than the entire NGC 7000 region, and the “wider FWHM region” has FWHM about 3 km s$^{-1}$ wider than other regions.

The southern and northern regions of LBN 391 possess obviously different RVs, with the RVs of H$\alpha$ emission lines of $-16.6$ km s$^{-1}$ and $-9.2$ km s$^{-1}$, respectively. The RV difference of the two regions is about 7 km s$^{-1}$, but their FWHMs are quite similar.

Several components in the Middle Region are also worth noting; the mean RV in the northern region (M1) is $-7.2$ km s$^{-1}$.
and the mean FWHM is 36.6 km s\(^{-1}\), and −13.0 km s\(^{-1}\) and 36.8 km s\(^{-1}\) in the southern region (M4) respectively. The RV difference is about 6 km s\(^{-1}\) between the southern and northern components, and their FWHMs are similar.

Table 2 compares the results of the previous literature mentioned in the Introduction with this work. The big differences appear only in the DEFPOS observations (Aksaker 2013). Aksaker et al. (2011) statistically analyzed the spectra of 10 nebulae with DEFPOS, and stated that the FWHMs in DEFPOS are 10 km s\(^{-1}\) wider than those in other literature, and the RV values differ approximately by 3 km s\(^{-1}\).

### 4.2. Features Revealed by Radial Velocity

Based on the results of RV spatial distributions (see Section 3.2), we have discovered a “curved feature” in the eastern extension of NGC 7000, and a “jet feature” extending from the LBN 391 nebula. Both the larger RV features are located beyond their bright nebulae and appear as narrow strips with uniform velocity components.

We have noticed that the larger RVs appear in the regions associated with outflow activities in bright nebula IC 5070 and dark cloud L935. Bally & Reipurth (2003) and Armond et al. (2011) discovered many HH objects in IC 5070, and Bally...
et al. (2014) also detected the MHOs in L935; a comparison of these multi-band observations may provide a hint for understanding the larger RV structures. All the features require more observations in the infrared and submillimeter wavelengths to explain their existence.

There are other notable features in the LBN 391 nebula. The position and direction of the “jet feature” in the RV map are consistent with the widest FWHM region (“M3”) in the FWHM map, and this “jet feature” appears at the boundary of the velocity differences between the northern and southern regions of LBN 391, but the “curved feature” extending to the east of NGC 7000 does not show wider FWHMs. All of these newly discovered characteristic structures require more observations and verification, and more comprehensive spectral observations of the LBN 391 nebula have been planned.

4.3. The “Wider FWHM Region” of NGC 7000

Based on the observational results of the FWHM distributions in Section 3.3, we have noticed an anomalous “wider FWHM region” in the eastern part of NGC 7000, consistent with the location of the Col428 cluster. The Col428 stellar cluster was first discovered by Collinder (1931) and classified as an open cluster. But later, Laugalys et al. (2007) concluded that Col428 is probably not a stellar cluster demonstrated through the distance and color–magnitude diagram, and Rebull et al. (2011) further pointed out that Col428 could not be a real young cluster because of a low disk fraction; both of them proposed that Col428 could not be taken as an independent entity but be a “window” in the molecular cloud. In this scenario, the “wider FWHM region” may be understood in that we are observing an optically thin region, and more components deeply detected in the H II region contribute to the line emissions.

For understanding the cause of “wider FWHM region”, we have tried to calculate further the gas temperature and non-thermal motion velocity. Based on the measured FWHMs toward H II regions, Reynolds et al. (1977) established a relationship between gas temperature and non-thermal motion (see Equations (4) and 5).

\[
T(K) = 23.5W_\text{H}^2\left(1 - \frac{W_\text{N}^2}{W_\text{H}^2}\right),
\]

\[
V(\text{km s}^{-1}) = 1.04W_\text{N}\left(1 - 0.071\frac{W_\text{H}^2}{W_\text{N}^2}\right)^{1/2},
\]

where \(W_\text{H}\) and \(W_\text{N}\) are the FWHMs of H\(_\alpha\) and [N II] emission lines, \(T\) is gas temperature, and \(V\) is non-thermal velocity.

The non-thermal motion velocities and gas temperatures have been calculated for the spectral points inside and outside the “wider FWHM region”, respectively. We note that, for the 195 statistical spectral points, 76 inside and 119 outside the “wider FWHM region”, the FWHM uncertainties are 1.6 \(\text{km s}^{-1}\) for H\(_\alpha\), and 2.5 \(\text{km s}^{-1}\) for [N II] emission lines, and all the calculated \(T\) and \(V\) are selected to be greater than three times the standard deviations. The uncertainties of \(T\) and \(V\) are calculated by following the usual error propagation equation. The results affirm that the “wider FWHM region” has a mean non-thermal velocity of \(20.5 \pm 2.9 \text{ km s}^{-1}\) and a mean temperature of \(10,269 \pm 3551 \text{ K}\), while the outside region of \(16.8 \pm 2.7 \text{ km s}^{-1}\) and \(9134 \pm 2794 \text{ K}\). Because the differences of non-thermal motion velocities and gas temperature are both not much bigger than the uncertainties, it seems hard to be sure which could be responsible for the “wider FWHM region”.

4.4. Features of the W80 Complex

The H\(_\alpha\) emission represents photoionization with dense ultraviolet photons in H II regions, and the [S II] forbidden line emission is commonly observed at the outer edge of nebulae. The nebular structures can be further revealed by comparing the intensities of [S II] and the H\(_\alpha\) emission lines.

Figure 14 presents the distributions of the log ([S II]/H\(_\alpha\)) ratios in the W80 region. There are two interesting features associated with the W80 complex. First, the minimum ratios are found to be distributed around the “W80 bubble”, appearing as a ring shape. The “W80 bubble” appears as an ionized bubble observed at radio wavelengths (Westerhout 1958), and its ionizing source is an O3.5 star (2MASS J20555125+4352246) (Comerón and Pasqualetti 2005).

A low [S II]/H\(_\alpha\) intensity ratio indicates relatively strong H\(_\alpha\) emissions, whereas a high ratio means relatively strong [S II] emissions. The ultraviolet photons from the central excitation source of a massive star ionize the surrounding gas to form stronger H\(_\alpha\) emission lines in the “W80 bubble” region, which results in a significant decrease of [S II]/H\(_\alpha\) ratios. Moreover, due to the occlusion of the high-density molecular cloud in the foreground, it shows a ring-shaped distribution centered on the excitable O-type star. Therefore, the ring-shape with low [S II]/H\(_\alpha\) ratios revealed by our spectral observations in the optical actually supports the “W80 bubble” structure observed by radio wavelengths.

In the western part of NGC 7000, there is also a region with low [S II]/H\(_\alpha\) ratios, associated with N6997, a dense young stellar cluster. The feature could provide evidence of abundant ultraviolet photons toward the direction of N6997.

Second, an increasing gradient of [S II]/H\(_\alpha\) ratios can be found from southwest to northeast in the NGC 7000 region. The increase of [S II]/H\(_\alpha\) ratios indicates enhancement of [S II] emission and the weakening of photoionization. We note that the strongest [S II] emissions at the northeastern edge of NGC 7000 (Figure 5) are consistent with the highest [S II]/H\(_\alpha\) ratios in Figure 14. The variations of the [S II]/H\(_\alpha\) ratios have been commonly observed, both in the ionization structure (Kewley et al. 2019) and in diffuse ionized gas (Otte et al. 2002). It is generally acknowledged that the hard ionizing radiation field
that escaped out of H II regions could produce strong [S II] line emissions (Kewley et al. 2019).

In addition, high [S II]/Hα ratios are prominent in the Middle Region. Blanc et al. (2009) pointed out that [S II]/Hα is observed to be greatly enhanced in diffuse ionized gas, and provided a mean [S II]/Hα ratio of 0.34, that is, $-0.46$ in log [S II]/Hα. The ratio seems just consistent with the measurements in the Middle Region in Figure 14.

5. Summary

The large-scale spectral observations of the H II regions are important for us to understand the star formation process and help study the environment of the whole W80 region. With LAMOST’s higher spectral resolution and wider FoV of 20 square degrees, we have built an almost complete spectral sample of the W80 emission nebulae. The results of this study are summarized as follows.

1. In the W80 region, based on the 3800 spectra by the LAMOST MRS-N, we obtain a total of 2982 nebular spectra with high enough S/N values, establishing the largest sample of spectral data up to date. We have measured the relative intensities, RVs, and FWHMs of the Hα, [N II], and [S II] emission lines for the W80 region, and have estimated as far as possible the electron densities for the W80 complex.

2. The spatial distributions of relative intensities in the W80 region show that the strongest line emissions are found in the bright nebular regions, like NGC 7000, IC 5070, and LBN 391; the weak line emissions also exist in the Middle Region, where no bright nebulae are detected in the wide-band optical observations. The strongest Hα emission in NGC 7000 is concentrated mainly in the central part, while the stronger [N II] and [S II] emissions tend to be distributed at the northeastern edge.

3. The spatial distributions of RVs in the W80 region show overall RV differences. The bright nebulae display RVs moving toward us, with the velocities mainly around $-25$ to $-15$ km s$^{-1}$. The Middle Region has RVs ranging from $-10$ to $0$ km s$^{-1}$, and some velocity components in the northern part are far away from us, with velocities ranging from $0$ to $+5$ km s$^{-1}$.

4. The spatial distributions of FWHMs in the W80 region also show overall differences, revealing that the FWHMs in the areas covered by the bright nebulae are narrower, mainly below 20 km s$^{-1}$; the FWHMs in the Middle Region are wider, above 30 km s$^{-1}$. In the Middle Region there exist several parts with the widest FWHM values ranging from 40 to 50 km s$^{-1}$.

5. The large-scale spectral observations toward the W80 region also reveal some unique structural features. A “curved feature” to the east of NGC 7000, and a “jet feature” to the west of LBN 391 are detected to be featuring larger approaching RVs. A “wider FWHM region” is identified in the eastern part of NGC 7000. The variations of [S II]/Hα ratios display a gradient from southwest to northeast in the NGC 7000 region, and manifest a ring shape around the “W80 bubble” in L935.
The new scientific findings by MRS-N provide useful information for researching the large-scale properties of HII regions. For complete data sets for the W80 region, we will conduct further spectral observations, and combine multi-band observations to investigate in detail the structural features.

Acknowledgments

The authors sincerely thank the anonymous referee for the great help that improved this paper. We also want to thank Xingchen Liu for the warmhearted help with data reduction and Hongchi Wang, Zhibo Jiang, Shaobo Zhang and Zhiwei Chen for scientific discussions.
