Established Facts

- Buerger disease, also called thromboangiitis obliterans, is an inflammatory and occlusive process involving small and medium size arteries and veins.
- The process can result in digital amputation.
- Involvement of nails is not common.

Novel Insights

- The first signs of thromboangiitis obliterans can appear at fingernails, showing chronic paronychia, onycholysis, and nail bed erosion.
- Dermatologist can make an early diagnosis, directing the patient to a pharmacological or an endovascular treatment.

Abstract

Introduction: Buerger disease, or thromboangiitis obliterans, is an inflammatory and occlusive process involving small and medium size arteries and veins, which generally affects the lower limbs of young adult male with the habit of smoking. Case Presentation: This paper reports 2 patients who developed nail lesions as the first sign of Buerger disease. Conclusion: Signs and symptoms of Buerger’s disease are secondary to the inflammatory process and arterial occlusion which results in severe ischemia. Involvement of nails is not common, but we found 2 different clinical features which have not been previously reported in the literature: chronic paronychia, and proximal leukonychia or onycholysis and nail bed erosion.
Introduction/Literature Review

Buerger disease is an inflammatory and occlusive process involving small and medium size arteries and veins, which generally affects the lower limbs of young adult male with the habit of smoking. Also called thromboangiitis obliterans, this nonatherosclerotic, segmental, inflammatory, and occlusive process often results in severe disability and digital amputation [1]. Involvement of nails is not common as the first clinical sign, and its differentiation from other causes of nail lesions is difficult. This paper reports 2 patients who developed nail lesions as the first sign of Buerger disease. Patients have given their written informed consent to publish their case (including publication of images).

Case Report 1

A 46-year-old Caucasian man was referred to our Department with a suspicion of onychomycosis involving the second and third fingernail. Clinical examination (Fig. 1a) revealed a paronychia in both fingers and a proximal leukonychia and hemorrhagic lesion at the fingertip of the third finger. The affected fingers were cold to the touch. The history revealed that the nail lesions had been present for 6 months and were associated with paresthesia and pain and the touch are cold. The patient also developed vice to smoke 20 cigarettes a day for many years and suffered from several episodes of left ilium pain while walking. Radiological examination of his right hand was normal. Vascular examination showed bilateral anterior and posterior tibial pulses, and the left popliteal pulse was not palpable. A vascular murmur was present in superficial and common femoral arteries. Laboratory analysis demonstrated an increased VES and fibrinogen. Arterial Dopplers of his right upper limb showed a decreased flow in the arterial palmar arch, and a very decreased flow in the first, third, and fourth interdigital arteries, as well as an absent flow in the second interdigital artery. All digital arteries showed absent flow. The patient was finally transferred to the Angiology Department with the diagnosis of Buerger disease in accord to Shionoya’s criteria [2]. Treatment with Prostavasin (60 mcg a day) for 11 days and Endoprost (0.05 mg a day) for 4 days did not produce significant improvement of pain and symptoms. Examination after 2 months (Fig. 1b) revealed onychomadesis and nail bed ulceration. The patient reduced but did not stop smoking.

Case Report 2

A 65-year-old Caucasian man was referred to our Department with a suspicion of malignant nail tumor involving the third fingernail. Clinical examination (Fig. 2) revealed onycholysis, erosion of the nail bed, presence of purulent exudate and marked chronic paronychia of the third fingernail.
erosion of the nail bed, presence of purulent exudate, with marked chronic paronychia in this fingernail, with a similar process also in the second fingernail, which presented onycholysis and exudation. Touching them, the fingers were cold. He declared that the lesion was present in the last 10 months. Medical history also confirms that the patient had been a smoker for many years. Radiological examination was normal. Vascular examination with Dopplers and angiography confirmed our suspicion of Buerger disease. He moved to another city, so unfortunately, we do not have data about the follow-up.

Discussion

Thromboangiitis obliterans is an uncommon, but not extremely rare vasculitis, which occurs more often in Asian countries and in young adult men smokers [3]. Its specific etiology remains obscure, but there are secondary etiologic factors which predispose to the disease, such as young age, male sex, oriental race, hereditary factors [4], autoimmune process [5], muscular occupation, changes in blood, drugs and poisons [6–8], and especially smoking. Burger’s disease has rarely been reported in nonsmokers and frequently improve associated factor. Perhaps a genetically controlled hypersensitivity to tobacco, due to a particular HLA phenotype, along with an impairment of sympathoadrenal function and an altered peripheral adrenergic response to cigarette smoking [9] are the trigger elements of this disease. This is then accelerated by various internal and external factors.

Signs and symptoms are secondary to the inflammatory process and arterial occlusion which results in severe ischemia. While the most frequent [10–12] are present in the lower extremity and visceral, our report underscores the importance of clinical manifestations in the nail [13–15]. We found 2 clinical signs, chronic paronychia and proximal leukonychia, which have not been previously reported in nonsmokers and frequently improve associated factor. Perhaps a genetically controlled hypersensitivity to tobacco, due to a particular HLA phenotype, along with an impairment of sympathoadrenal function and an altered peripheral adrenergic response to cigarette smoking [9] are the trigger elements of this disease. This is then accelerated by various internal and external factors.

In our cases, the first signs of thromboangiitis obliterans appeared at fingernails, with chronic paronychia and leukonychia in the first case, onycholysis and nail bed erosion in the second. In our opinion, chronic paronychia and erosion could be a consequence of digital ischemia and inflammation producing trophic lesion in periungual tissues and nail bed and leukonychia could be consequence of abnormalities in keratinization due to nail matrix damage. In our patients, the fingers involved are the first and second fingers, and we postulate that the explanation is due because these fingers are the ones used to hold the cigarette when 1 smokes. We would like to stress the nails should be examined in patients affected by vascular disease because their changes may represent the first sign of blood supply impairment.

Dermatologist can make an early diagnosis, increasing the success of pharmacologic treatment and endovascular revascularization, reducing the risk of minor and major amputation [17, 18]. In particular, the association between chronic paronychia, leukonychia, nail bed erosion, and cold fingers should aware the physician to the possibility of a peripheral vascular disease [19, 20].

Statement of Ethics

Subjects have given their written informed consent to publish their case (including publication of images). Ethical approval was not required for this study in accordance with national guidelines.

Conflict of Interest Statement

The authors have no conflicts of interest to declare.

Funding Sources

No funding sources to declare.

Author Contributions

Every author contributed equally in the manuscript, for writing and editing the paper.

Data Availability Statement

All data generated during this study are included in this article. Further enquiries can be directed to the corresponding author.
