ABSTRACT
This paper demonstrates a hafnium zirconium oxide (HZO)-based ferroelectric NEMS unimorph as the fundamental building block for very low-energy capacitive readout in-memory computing. The reported device consists of a $250 \times 30 \, \mu m^2$ unimorph cantilever with 20-nm-thick ferroelectric HZO on 1 $\mu m$ SiO$_2$. Partial ferroelectric switching in HZO achieves analog programmable control of the piezoelectric coefficient ($d_{31}$), which serves as the computational weight for multiply accumulate (MAC) operations. The displacement of the piezoelectric unimorph was recorded by actuating the device with different input voltages $V_{in}$. The resulting displacement was measured as a function of the ferroelectric programming/poling voltage $V_p$. The slopes of central beam displacement ($\delta_{max}$) vs $V_{in}$ were measured to be between $182.9 \, nm/V$ (for $\sim 8 \, V_p$) and $-90.5 \, nm/V$ (for $8 \, V_p$), which corresponds to displacement proportionality constant $b$ of $68 \, nm/V^2$ for $+ve \, V_p$ and $47 \, nm/V^2$ for $-ve \, V_p$, demonstrating linear behavior of the multiplier unit. The resultant $\delta_{max}$ from AC actuation is in the range of $\sim 18$ to 36 nm and is a scaled product of $V_{in}$ and $d_{31}$ (governed by the $V_p$). The multiplication function serves as the fundamental unit for MAC operations with the ferroelectric NEMS unimorph. The displacement from many such beams can be added by summing the capacitance changes, providing a pathway to implement a multi-input and multi-weight neuron. A scaling and fabrication analysis suggests that this device can be CMOS compatible, achieving high in-memory computational throughput.

Neuromorphic computation is of great interest to computing theory and practical implementations due to the potential for low-power, high efficiency, and small form factor information processing with deep neural networks (DNNs). The building blocks of DNNs are perceptron blocks, which inherently necessitate brain-like synaptic functions achieved through arrays of multiply accumulate (MAC) units. With the ever-increasing number of variables required for neuromorphic computation with high accuracy, there is an urgent need to develop highly energy-efficient device architectures. The energy used per MAC unit is, therefore, a useful metric to compare technologies. Ferroelectric field-effect transistors (Fe-FET) have been used to mimic analog synaptic operation with gate-ferroelectric switching in silicon and germanium channel devices to realize multi-level conductance modulation with potentiation and depression with 50–100 ns switching pulses and 3–5 MV/cm fields. FET-based in-memory computation architectures are susceptible to large read and write energy consumption and high leakage currents in idle mode, particularly with gate dielectric thickness scaling down to <5 nm. Resistive random access memory (RRAM) enables neuromorphic synaptic functionality but necessitates current-based control circuitry that can limit the dynamic range and the effective number of bits. Nano Electro-Mechanical Systems (NEMS) switches and beams offer an alternate pathway to zero-leakage in-memory compute synaptic functionality, provided that the beam actuation has embedded programmable weights in the form of tunable capacitive or piezoelectric coupling. Such switches are especially useful where infrequent update of neuromorphic weights is needed and the analog programming can be done at DC or low frequencies. We have previously reported a graphene-on-HZO ferroelectric device that uses potential gradients across the graphene to achieve fractional switching, with the modulated graphene resistance also used for resistive memory readout. While analog in-memory computing has been demonstrated using different architectures that use transistors or memristors, few prior works have used an NEMS-based approach that takes advantage of a released beam structure to eliminate energy leakage in an idle state. In previous work, the idea of using nanomechanical electrostatic actuators to
produce MAC units has been described. In contrast, we present a ferroelectric/piezoelectric beam transducer to enable the multiplication that can be readout capacitively, eliminating any DC currents.

This paper presents a technique to store the neural net weights in the form of the programmable piezoelectric coefficient $d_{31}$ of an HZO-driven unimorph. Similar to a fixed–free unimorph, the fixed–fixed unimorph displacement is proportional to $d_{31}$. The $d_{31}$ is modulated by applying a polarization switching voltage $V_p$. After polarization programming, different actuation inputs ($V_{in}$) actuate the cantilever such that the unimorph displacement is a scaled product of $V_p$ and $V_{in}$. The displacement can in turn be measured as capacitive sense current from a capacitive divider circuit, for massively parallel MAC operations from arrays of such NEMS elements. Figure 1 shows the concept of the partial polarization in a ferroelectric for analog control of beam-bending in a unimorph. In addition to the active ferroelectric film, the unimorph stack also includes metal contact layers and an insulating elastic layer. The polarization vs E-field (PE loop) for an 80 μm diameter metal–ferroelectric–metal (MFM) capacitor on a 20-nm-thick HZO film is shown in Fig. 1(a). Moving counterclockwise along the PE loop starting with all dipoles point downward (point O), the film can be in a state of net-zero polarization (points A and A′) at the positive and negative coercive fields, fully down- or up-switched (points C and C′) or partially polarized (along the slopes of A–B and A′–B′). Each point along the PE loop achieves a specific macroscopic value of $d_{31}$, with the maximum and minimum values at the two extrema (at points C and C′) using the appropriate choice of poling voltage $V_p = E_p HZO$. After programming, if a much smaller actuation voltage $V_{in}$ is applied such that it produces no dipole switching, an in-plane stress is generated due to expansion or contraction of the HZO film along its length, resulting in the piezoelectric bending moment $M_{Piezo}$. The programming would enable weight-storage in DNNs at reduced rates compared to inference events.

For a given $V_p$ and $V_{in}$ the NEMS beam displacement is, a scaled product of weights and inputs (detailed derivation in the supplementary material, Sec. IA)

$$\delta_{max} = \beta \cdot V_p \cdot V_{in}.$$  (1)

Here, $\beta$ is the displacement proportionality constant that depends on ferroelectric material properties, beam geometry, Young’s modulus, etc. We can design the multiplier to achieve linear behavior in the transfer characteristics curve along the rising and falling slopes of the PE loop to accomplish a multiplicative function for parallel MAC operations. Figure 1(c) represents the multiplier unit with a capacitive readout to measure the output voltage. The left and right beams are poled with the same voltage amplitude but opposite polarity. Thus, for the same input voltage $V_{in}$ the left and right beams displace such that the difference between the two represents the product of $V_{in}$ and $V_p$. The differential motion causes differential capacitance between left and right capacitive parallel plates. The output voltage is given by

$$V_{out} = V_{dd} \cdot \frac{C_l - C_R}{C_l + C_R} \approx V_{dd} \cdot \frac{\delta_{max, L} - \delta_{max, R}}{2g} = SF \cdot V_p \cdot V_{in}.$$  (2)

Here, $\delta_{max, L}$ and $\delta_{max, R}$ are left and right beam center displacements with initial gap $g$. $\gamma$ is an constant, which relates $\delta_{max}$ to the parallel plate displacement at sense electrode (see the supplementary material, Sec. IA, for detailed derivation). Several multiplier units can then be
further connected in parallel with an activation unit to form a perceptron. The output voltage of the MAC unit [Fig. 1(d)] is

$$V_{\text{out,MAC}} = V_{dd} \sum_{i=1}^{N} C_{L,i} - \sum_{i=1}^{N} C_{R,i} = SF \sum_{i=1}^{N} V_{p,i} \cdot V_{in,i}. \quad (3)$$

Figures 2(a) and 2(b) show the top and cross section views, respectively, of the clamped-clamped ferroelectric unimorph used to demonstrate piezoelectric coefficient programming. 1-µm-thick thermal SiO$_2$ forms the elastic layer underneath 20 nm ferroelectric HZO. The HZO is capped by 3 nm of alumina (Al$_2$O$_3$), followed by annealing at 400 °C to crystallize the HZO in its ferroelectric orthorhombic phase. 200 nm platinum (Pt) and 100 nm aluminum (Al) were deposited to form the bottom and top metal contacts for the HZO, respectively. The beam was released by isotropic etching of the silicon substrate using Xactix XeF$_2$ etcher (full process flow shown in the supplementary material, Sec. II). A scanning electron microscope image of the fabricated device is shown in Fig. 2(c). After release, the beams were observed to buckle due to residual film-stress generated during microfabrication. A 3D optical profilometer (Zygo™ system) was used to measure the beam buckling profile [Fig. 2(d)]. The observed center-buckling for a 250 × 30 µm$^2$ was 4.98 µm.

HZO ferroelectric characterization was performed using a Sawyer–Tower circuit configuration on a custom probe station with 3D profile of the released beam measured using Zygo™. The output voltage of the MAC unit forms the elastic layer underneath 20 nm ferroelectric HZO. The PUND input signal has rise, fall, and wait times corresponding to 1 kHz PUND frequency, and a peak-to-peak amplitude of 15 V. Figure 3(a) shows time-domain input voltage and output sense current measured with an 11.8 kΩ sense resistor. The P and N pulses show a switching current peak below the peak voltage, indicative of polarization switching, whereas the U and D pulses show capacitive displacement current and low leakage. This confirms ferroelectricity in the released HZO films without any degradation, consistent over more than 10,000 cycles of switching with CW operation. Figure 3(b) plots the switching current density (J) vs E-field. The PUND measurement was performed on multiple such released NEMS beams with a range of lengths from 100 to 400 µm and widths spanning 15–39 µm. The overlay from these measurements is shown with multiple dotted lines in Fig. 3(c). For comparison, the PUND loop for an unreleased 80 µm diameter circular electrode is also shown on the same plot (solid black line). This shows that there is little/no degradation of ferroelectric properties of the HZO before and after release; $P_r$ is unchanged and $E_C$ has a small increase in ~14%, a likely result of the reduced slope-steepness of the PE curve, due to stress relief in released devices. Multiple release devices with different electrode sizes show overlapping loops suggesting high repeatability. PUND measurements yield an extracted $E_i$ = 1.5 MV/cm and $P_r$ = 10 µC/cm$^2$, consistent with previously reported values. The devices were also tested for DC breakdown as shown in Fig. 3(d). The device’s current density exceeds 10 µA/cm$^2$ at 3.15 MV/cm.

The central concept of this work is to use analog weight storage in the bending motion of the NEMS beam for in-memory computation, which relies on the programming of the $d_{31}$ coefficient of the device by using different poling voltages. The test methodology used for this experiment is as follows:

**Step 1:** Device poling with CW single-sided pulses at 3 kHz. The configuration used for poling is depicted in Fig. 3(a) (inset). The test signal is applied to the top electrode, and the ground
connection is made to the bottom electrode by breaking down the HZO under a large top metal pad to short it to the bottom electrode.

Step 2: Beam actuation with a small $V_{in}$ to measure the displacement amplitude, without additional polarization switching.

Step 3: Increase poling voltage by 0.5 V and repeat steps 1–2, while tracing the PE loop counterclockwise from $0 \text{V} \rightarrow 8 \text{V} \rightarrow 0 \text{V}$

This voltage sweep for $V_p$ is similar to the PUND loop with one key difference. In this technique, we stepped the $V_p$ by 0.5 V and then measured the beam displacement with a fixed $V_{in}$ amplitude, unlike the PUND measurements in CW operation with increasing voltages.

A Polytec MSA-400 laser Doppler vibrometer (LDV) was used to measure the beam motion. For a $250 \times 30 \mu m^2$ beam, a 0.1 V amplitude frequency chirp from 1 kHz to 1 MHz was applied. A resonance at $f_0 = 455.23$ kHz was identified with a quality factor of $Q = 305$. After each poling, AC voltage $V_{in}=0.1$ V was used to actuate and measure amplified beam displacement at $f_0$, to achieve improved displacement resolution compared to low-frequency or DC actuation.

Figure 4(a) shows the peak beam displacement $d_{max}$ and resonant frequency $f_0$ vs poling voltage $V_p$ plot for the nominal $250 \times 30 \mu m^2$ ferroelectric clamped–clamped beam. $d_{max}$ (red line) is modulated for different values of $V_p$ and traces a hysteresis loop, similar to the PE loop from PUND measurements. The net effect of the number of upward and downward pointing dipoles that control the macroscopic polarization in the beam (induced due to $V_p$) also changes the beam stiffness resulting in resonance frequency modulation (black line), which presents a separate modality of weight storage in the beam. The two dips in $f_0$ correspond to the positive and negative coercive fields of the HZO film, where the net polarization is almost zero. As illustrated in Fig. 1(b), domain randomization is a potential cause for likely film relaxation at these points causing $f_0$ to drop.

From Fig. 4(a), the positive linear dependence of $d_{max}$ can be seen in the voltage interval $2.5 \text{V} \rightarrow 8 \text{V}$ (rising slope). Similarly, negative linear dependence in the interval $-2.5 \text{V} \rightarrow -8 \text{V}$ (falling slope). Here, the slope of $d_{max}$ vs $V_p$ for constant $V_{in}$ is $\beta$ as defined in Eq. (1). The effect of $V_{in}$ on $d_{max}$ is explained in paragraph. Two points were selected on the positive slope to show the resonance vibration magnitude and phase plots of the vibrating beam [Fig. 4(b)]. Points 1 and 2 have nearly the same displacement magnitude but exactly opposite phases. This $180^\circ$ phase difference is a signature of polarization
inversion corresponding to a sign change for \( \delta_{\text{max}} \). To show the effect of \( V_{\text{in}} \) on \( \delta_{\text{max}} \), \( V_{\text{in}} \) was swept from 0.02 to 0.20 V for different values of the \( V_p \) [Fig. 5(a)].

Figure 5(a) plots \( \delta_{\text{max}} \) vs \( V_{\text{in}} \) at different values of \( V_p \), which emulates the transfer characteristics of the analog multiplier. For a fixed poling voltage, an input voltage sweep yields a linear increase in displacement value. Similarly, for constant inputs, different poling voltages outputs different displacement values. The slope of the plot in Fig. 5(a) is the experimental \( \beta/C_p V_p \). We can calculate the displacement proportionality constant \( \beta \) from Fig. 5(a) as follows:

\[
\beta = \frac{\delta_{\text{max}}}{V_p V_{\text{in}}}
\]  

Equation (4) demonstrates that \( \delta_{\text{max}} \) is the scaled product of inputs (\( V_{\text{in}} \)) and weights (\( V_p \)). This is a linear equation in the range of \(-5.5 \) to \(8 V\) for the device tested here (250 \( \times \) 30 \( \mu \)m\(^2\) beam).

In conclusion, we have demonstrated the working of an HZO-based NEMS multiplier with weight storage functionality. The device was fabricated and tested to prove the dependence of beam displacement on the poling voltage of the ferroelectric film. Polarization-dependent
frequency-tuning was also observed, which can be further explored to achieve an electrically reconfigurable filter. For a $250 \times 30 \mu\text{m}^2$ beam poled at $8\,\text{V}$, $\delta_{\text{max}} = 18\,\text{nm}$ and $f_0 = 455.23\,\text{kHz}$ was measured with a $Q = 305$. The $\delta_{\text{max}}$ vs $V_{\text{in}}$ plot at different values of $V_p$ demonstrate the operation of an analog NEMS multiplier. While this study uses AC actuation of the beam, in the future, DC input voltages are anticipated for DNN applications. A capacitive readout of the beam motion can be used instead of a topical readout for much higher resolution [as illustrated in Fig. 1(c)].

The dimensional and voltage scaling of the prototype device demonstrated is critical for CMOS-integrated adoption while maximizing computational throughput. For CMOS compatibility, <1 V operation is necessary. This sets an upper bound for HZO film thickness of <7 nm for $E_p = 1.5\,\text{MV/cm}$. Non-resonant actuation of the devices would require a settling time of $2Qf_0$. Assuming two operations per device, multiplication and addition, the computation speed of a single device given by $1/C_{\text{HZO}} \cdot V^2_{\text{in}}$. For example, a unimorph device of size $5 \times 0.5\,\text{mm}^2$ and thickness $28\,\text{nm}$ ($4 \times 4$ HZO thickness) with a $Q = 10$, which can be realized by high-pressure gas damping, yields $f_0 \approx 20\,\text{MHz}$ and computation speed of 2 MFLOPS/device. Considering driving electrodes of size $1 \times 0.3\,\text{mm}$ with 7-nm-thick HZO between $V_{\text{in}}$ ($0.1\,\text{V}$) and GND electrodes, the energy consumption per operation can be estimated as $E = \frac{1}{2} C_{\text{HZO}} \cdot V^2_{\text{in}}$, respectively. Here, $E$ is the energy consumption per operation for an individual device given by $\frac{1}{2} C_{\text{HZO}} \cdot V^2_{\text{in}}$, where $f_0$ is the operating frequency. This computation speed with ultra-low energy consumption and zero leakage current will pave the path toward brain-level computation efficiency.

See the supplementary material for further details.
