ABSTRACT

We have constructed the first all-sky map of the thermal Sunyaev-Zeldovich (tSZ) effect by applying specifically tailored component separation algorithms to the 100 to 857 GHz frequency channel maps from the Planck survey. This map shows an obvious galaxy cluster tSZ signal that is well matched with blindly detected clusters in the Planck SZ catalogue. To characterize the signal in the tSZ map we have computed its angular power spectrum and high-order statistics. At large angular scales ($\ell < 60$), the major foreground contaminant is the diffuse thermal dust emission. At small angular scales ($\ell > 60$) the power spectrum is consistent with that expected from the Planck catalogue of SZ sources, with clear evidence of additional signal from unresolved clusters and, potentially, diffuse warm baryons. Marginalized band-powers of the Planck tSZ power spectrum and the best-fit model are given. We use the tSZ power spectrum to obtain the following cosmological constraint: $\sigma_8(\Omega_m/0.28)^{1/2} = 0.784 \pm 0.016 (68\% C.L.)$. This result is in weak tension at (2.7 $\sigma$) with the Planck measurements of the primary anisotropies in the cosmic microwave background. The non-Gaussianity of the Compton parameter map is further characterized by computing its 1D probability distribution function and its bispectrum. These are used to place additional independent constraints on $\sigma_8$.

Key words. cosmological parameters – large-scale structure of Universe – Galaxies: clusters: general
1. Introduction

This paper, one of a set associated with the 2013 release of data from the Planck mission [Planck Collaboration I (2013)], describes the construction of a Compton y parameter map and the determination of its angular power spectrum and high-order statistics.

The thermal Sunyaev-Zeldovich (tSZ) effect (Sunyaev & Zeldovich, 1972), produced by the inverse Compton scattering of cosmic microwave background (CMB) photons by hot electrons along the line of sight, has proved to be a major tool for studying the physics of clusters of galaxies as well as structure formation in the Universe. In particular, tSZ-selected catalogues of clusters of galaxies have been provided by various experiments including the Planck satellite (Planck Collaboration VIII [2011] Planck Collaboration XXIX [2013]), the Atacama Cosmology Telescope (ACT, Hasselfield et al. [2013]) and the South Pole Telescope (SPT, Reichardt et al. [2013]). These catalogues and their associated sky surveys have been used to study the physics of clusters of galaxies (Planck Collaboration XII [2011] Planck Collaboration XI [2011] Planck Collaboration X [2011]) and their cosmological implications (Planck Collaboration XX [2013] Benson et al. [2013], Das et al. [2013], Wilson et al. [2012], Mak & Pierpaoli [2012]).

The study of number counts and their evolution with redshift using tSZ detected clusters of galaxies is an important cosmological test (Carlstrom et al. [2002], Dunkley et al. [2013], Benson et al. [2013] Planck Collaboration XX [2013]). The measurement of the tSZ effect power spectrum has been proposed by Komatsu & Seljak [2002] as a complement to the counts. One advantage of using the tSZ angular power spectrum over cluster counts is that no explicit measurement of cluster masses is required. Also, lower mass, and therefore fainter, clusters, which may not be detected as individual objects, contribute to this statistical signal. Benson et al. [2013] and their associated sky surveys have been used to study the physics of clusters of galaxies (Planck Collaboration XII [2011] Planck Collaboration XI [2011] Planck Collaboration X [2011]) and their cosmological implications (Planck Collaboration XX [2013] Benson et al. [2013], Das et al. [2013], Wilson et al. [2012], Mak & Pierpaoli [2012]).

To date, measurements of the tSZ power spectrum are only available from high resolution CMB-oriented experiments like ACT (Sievers et al. [2013]) and SPT (Reichardt et al. [2012]). In these studies, constraints on the amplitude of the tSZ power spectrum at $f = 3000$ are obtained by fitting a tSZ template in addition to other components (i.e., CMB, radio and infrared point-source and clustered cosmic infrared background, CIB) to the measured total power spectrum. These constraints are obtained at angular scales where the tSZ signal dominates over the CMB, but at these same scales the contamination from point sources and the clustered CIB is important and may affect the measured tSZ signal. Moreover, the scales probed are particularly sensitive to the uncertainties in modelling the intracluster medium (ICM) over a broad range of masses and redshifts, and at large cluster-centric radii (Battaglia et al. [2010]). Recent work, using hydrodynamical simulations (Battaglia et al. [2010], Battaglia et al. [2012]) $N$-body simulations plus semi-analytic gas models (Trac et al. [2011]) and purely analytic models (Shaw et al. [2010]), have significantly reduced the tension between the observed and predicted values. However, the distribution of amplitudes between different models and simulations is still significantly larger than the measurement errors, degrading the constraints that can be placed on cosmological parameters with these methods (Dunkley et al. [2013], Reichardt et al. [2013]).

In addition to the power spectrum, and (as pointed out in Rubino-Martín & Sunyaev [2003]), the skewness or, equivalently, the bispectrum of the tSZ signal and an independent tool to study and to isolate the signal of clusters, separating it from the contribution of radio and IR sources. Recently, Bhattacharya et al. [2012] showed that the bispectrum of the tSZ effect signal is dominated by massive clusters at intermediate redshifts, for which high-precision X-ray observations exist. This contrasts with the power spectrum, where the signal mainly comes from the lower mass and higher redshift groups and clusters (e.g., Trac et al. [2011]). The theoretical uncertainty in the tSZ bispectrum is thus expected to be significantly smaller than that of the SZ power spectrum. Combined measurements of the power spectrum and the bispectrum can thus be used to distinguish the contribution to the power spectrum from different cluster masses and redshift ranges. The bispectrum amplitude scales as $\sigma_{8}^{10-12}$ (Bhattacharya et al. [2012]). Measurements of the tSZ bispectrum have been reported by the SPT collaboration (Crawford et al. [2013]). Alternatively, Wilson et al. [2012] used the unnormalized skewness of the tSZ fluctuations, $(\gamma_{n})$, which scales approximately as $\sigma_{8}^{11}$, to obtain an independent determination of $\sigma_{8}$.

Thanks to its all-sky coverage and unprecedented wide frequency range, Planck has the unique ability to produce an all-sky tSZ Compton parameter ($y$) map and an accurate measurement of the tSZ power spectrum at intermediate and large angular scales, for which the tSZ fluctuations are almost insensitive to the cluster core physics. The Planck Compton parameter map also offers the possibility of studying the properties of the non-Gaussianity of the tSZ signal using higher order statistical estimators, such as the skewness and the bispectrum. In this paper we construct a tSZ all-sky map from the individual Planck frequency maps and compute its power spectrum, its 1D probability density function (1D PDF), and the associated bispectrum.

The paper is structured as follows. Section 2 describes the Planck data used to compute the tSZ all-sky map and the simulations used to characterize it. We discuss details of the modelling of the tSZ effect power spectrum and bispectrum in Sect. 3. In Sect. 4 we present the Planck all-sky Compton parameter map. Section 5 describes the power spectrum analysis. Cross-checks using high-order statistics are presented in Sect. 6. Cosmological interpretation of the results is discussed in Sect. 7 and we present our conclusions in Sect. 8.

---

1 Planck ([http://www.esa.int/Planck](http://www.esa.int/Planck)) is a project of the European Space Agency (ESA) with instruments provided by two scientific consortia funded by ESA member states (in particular the lead countries France and Italy), with contributions from NASA (USA) and telescope reflectors provided by a collaboration between ESA and a scientific consortium led and funded by Denmark.

2. Data and simulations

2.1. The Planck data

This paper is based on the first 15.5 months of Planck's mission, corresponding to more than two full-sky surveys. We refer to Planck Collaboration II (2013), Planck Collaboration III (2013), Planck Collaboration V (2013), Planck Collaboration VIII (2013), Planck Collaboration IX (2013), and Planck Collaboration VI (2013) for the generic scheme of time-ordered information processing and map-making, as well as for the technical characteristics of the Planck frequency maps. The Planck channel maps are provided in HEALPix (Gorski et al. 2005) pixelization scheme at \( N_{\text{side}} = 2048 \). An error map is associated with each channel map and is obtained from the difference of maps made from the first and second half of each ring (stable point period). The difference maps, called half-ring or null maps, are mainly free from astrophysical emission and they are a good representation of the statistical instrumental noise. Null maps have also been used to estimate the noise in the final Compton parameter maps. Here we approximate the Planck effective beams by circular Gaussians (Planck Collaboration IV [2013], Planck Collaboration VII [2013]). The FWHM values for each frequency channel are given in Table 1. Although tests have been performed using both LFI and HFI channel maps, the work presented here is based mostly on HFI data.

2.2. FFP6 Simulations

We also use simulated Planck frequency maps obtained from the Full Focal Plane (FFP6) simulations, which are described in the Planck Explanatory Supplement (Planck Collaboration ES [2013]). These simulations include the most sky components at microwave and millimetre frequencies, based on foregrounds from the Planck Sky Model (PSM, Delabrouille et al. [2013]): CMB; thermal SZ effect; diffuse Galactic emissions (synchronotron, free-free, thermal and spinning dust and CO); radio and infrared point sources, and the clustered CIB. The simulated tSZ signal was constructed using hydrodynamical simulations of clusters of galaxies up to redshift 0.3, completed with pressure profile-based simulations of individual clusters of galaxies randomly drawn on the sky. The noise in the obtained maps was realized using Gaussian random noise in the time domain and therefore accounts for noise inhomogeneities in the maps.

3. Modelling the tSZ effect

The thermal SZ Compton parameter in a given direction, \( \mathbf{n} \), is

\[
y(\mathbf{n}) = \sum_{l,m} y_{lm} Y_{lm}(\mathbf{n}).
\]

Thus, the angular power spectrum of the Compton parameter map is

\[
C_{\ell}^{SZ} = \frac{1}{2 \ell + 1} \sum_{m} y_{lm} y_{lm}^*.
\]

Note that \( C_{\ell}^{SZ} \) is a dimensionless quantity here, like \( y \).

To model the tSZ power spectrum we consider a 2-halo model to account for intra-halo and inter-halo correlations:

\[
C_{\ell}^{SZ} = C_{\ell}^{1\text{halo}} + C_{\ell}^{2\text{halos}}.
\]

The 1-halo term, also known as the Poissonian contribution, can be computed by summing the square of the Fourier transform of the projected SZ profile, weighted by the number density of clusters of a given mass and redshift (Komatsu & Seljak 2002):

\[
C_{\ell}^{1\text{halo}} = \int_{0}^{\Delta_{\text{max}}} dz dV_c \int_{M_{\text{min}}}^{M_{\text{max}}} dM \frac{dn(M,z)}{dM} \left| \hat{y}(M,z) \right|^2.
\]

where \( dV_c = dz d\Omega \) is the comoving volume per unit redshift and solid angle and \( n(M,z) dM dV_c = dz dz dV_c(z) \) is the probability of having a galaxy cluster of mass \( M \) at a redshift \( z \) in the direction \( d\Omega \). The quantity \( \hat{y} = \hat{y}(M,z) \) is the 2D Fourier transform on the sphere of the 3D radial profile of the Compton \( y \)-parameter of individual clusters,

\[
\hat{y}(M,z) = \frac{4\pi r_s}{t_s} \left( \frac{\sigma_T}{m_e c^2} \right) \int_{0}^{\infty} dx x^2 P_e(z,x,s) \sin(\ell/x \ell_s) \ell / \ell_s.
\]

where \( x = r/r_s, \ell_s = D_A(z)/r_s, r_s \) is the scale radius of the 3D pressure profile, \( D_A(z) \) is the angular diameter distance to redshift \( z \) and \( P_e \) is the electron pressure profile.

The 2-halo term is obtained by computing the correlation between two different halos (Komatsu & Kitayama [1999], Diego & Majumdar [2004], Taburet et al. 2011):

\[
C_{\ell}^{2\text{halos}} = \int_{0}^{\Delta_{\text{max}}} dz dV_c \left[ \int_{M_{\text{min}}}^{M_{\text{max}}} dM \frac{dn(M,z)}{dM} \left| \hat{y}(M,z) \right|^2 \right] P(k,z),
\]

where \( P(k,z) \) is the 3D matter power spectrum at redshift \( z \). Here \( B(k,z) \) is the time-dependent linear bias factor that relates the matter power spectrum, \( P(k,z) \), to the power spectrum of the cluster correlation function. Following Komatsu & Kitayama [1999], see also Mo & White [1996] we adopt \( B(k,z) = 1 + (v^2(M,z) - 1) / \delta_c(z) \), where \( v^2(M,z) = \delta_c(M)/D_A(z) \) is the present-day rms mass fluctuation, \( D_A(z) \) is the linear growth factor, and \( \delta_c(z) \) is the threshold over-density of spherical collapse.

Finally, we compute the tSZ power spectrum using the mass function \( dn(M,z)/dM \) including an observed-to-true mass bias of 20%, as discussed in detail in Planck Collaboration XX [2013], and we model the SZ Compton parameter using the pressure profile of Arnaud et al. [2010]. This approach is adopted in order to be consistent with the ingredients of the cluster number count analysis in Planck Collaboration XX [2013].

3.1. tSZ power spectrum

Decomposing the map in spherical harmonics, \( Y_{lm} \), we obtain

\[
y(\mathbf{n}) = \sum_{l,m} y_{lm} Y_{lm}(\mathbf{n}).
\]

Thus, the angular power spectrum of the Compton parameter map is

\[
C_{\ell}^{SZ} = \frac{1}{2 \ell + 1} \sum_{m} y_{lm} y_{lm}^*.
\]
3.2. \( N \)th moment of the tSZ field

To calculate the \( N \)th moment of the tSZ field, we assume, to first order, that the distribution of clusters on the sky can be adequately described by a Poisson distribution corresponding to the 1-halo term. We neglect the contribution due to clustering between clusters and their overlap (Komatsu & Kitayama 1999). The \( N \)th moment is then given by (Wilson et al. 2012)

\[
\int_0^{\Omega_{\text{max}}} d\Omega \frac{dV_c}{d\Omega} \sum_{n_{\text{max}}} M_{\text{max}} \frac{dn(M,z)}{dM} \int d^2y \gamma(\theta, M, z)^N,
\]

where \( \gamma(\theta, M, z) \) is the integrated Compton parameter along the line of sight for a cluster of mass \( M \) at redshift \( z \).

3.3. Bispectrum

The angular bispectrum, analogous to the 3-point correlation function in harmonic space, is the lowest-order indicator of the non-Gaussianity of a field. It is given by (Bhattacharya et al. 2012)

\[
B_{\ell_1,\ell_2,\ell_3}^{m_1,m_2,m_3} = \langle \hat{y}_{\ell_1,m_1} \hat{y}_{\ell_2,m_2} \hat{y}_{\ell_3,m_3} \rangle,
\]

where the angle-averaged quantity in the full-sky limit can be written as

\[
b(\ell_1, \ell_2, \ell_3) = \sum_{m_1,m_2,m_3} \left( \begin{array}{ccc} \ell_1 & \ell_2 & \ell_3 \\ m_1 & m_2 & m_3 \end{array} \right) B_{\ell_1,\ell_2,\ell_3}^{m_1,m_2,m_3},
\]

which has to satisfy the conditions \( m_1 + m_2 + m_3 = 0 \), \( \ell_1 + \ell_2 + \ell_3 = \text{even} \), and \( |\ell_1 - \ell_2| \leq \ell_1 \leq \ell_1 + \ell_2 \), for the Wigner 3j function in brackets. For illustration we compute the bispectrum assuming a Poissonian distribution, given by (Bhattacharya et al. 2012)

\[
b(\ell_1, \ell_2, \ell_3) = \frac{1}{4} \left( \begin{array}{ccc} \ell_1 & 0 & \ell_3 \\ 0 & \ell_2 & 0 \end{array} \right)
\]

\[
\int_0^{\Omega_{\text{max}}} d\Omega \frac{dV_c}{d\Omega} \sum_{n_{\text{max}}} M_{\text{max}} \frac{dn(M,z)}{dM} \tilde{y}_{\ell_1}(M,z) \tilde{y}_{\ell_2}(M,z) \tilde{y}_{\ell_3}(M,z).
\]

4. The reconstructed all-sky tSZ map

4.1. Reconstruction methods

The contribution of the tSZ effect in the Planck frequency maps is subdominant with respect to the CMB and other foreground emissions. Furthermore, the tSZ effect from galaxy clusters is spatially localized and leads to a highly non-Gaussian field with respect to that from the CMB, CMB-oriented component-separation methods (Planck Collaboration XII 2013) are not optimized to recover the tSZ signal. We therefore need to use specifically tailored component separation algorithms that are able to reconstruct the tSZ signal from the Planck frequency channel maps. These optimized all-sky component separation techniques rely on the spatial localization of the different astrophysical components and on their spectral diversity to separate them. We present in the following, the results of two algorithms, MILCA (Modified Internal Linear Combination Algorithm, Hurier et al. 2013) and NILC (Needlet Independent Linear Combination, Remazeilles et al. 2011). Both are based on the well-known Internal Linear Combination (ILC) approach that searches for the linear combination of the input maps that minimizes the variance of the final reconstructed map under the constraint of offering unit gain to the component of interest (here the tSZ effect, whose frequency dependence is known). Both algorithms have been extensively tested on simulated Planck data.

4.1.1. MILCA

MILCA (Hurier et al. 2013) uses two constraints: preservation of the tSZ signal, assuming the tSZ spectral signature; and removal of the CMB contamination in the final SZ map, making use of the well-known spectrum of the CMB. In addition, to compute the weights of the linear combination, we have used the extra degrees of freedom in the linear system to minimize residuals from other components (two degrees of freedom) and from the noise (two additional degrees). The noise covariance matrix was estimated from the null maps described in Section [2]. To improve the efficiency of the MILCA algorithm, weights are allowed to vary as a function of multipole \( \ell \), and are computed independently on different sky regions. We have used 11 filters in \( \ell \) space, with an overall transmission of one, except for \( \ell < 8 \). For these large angular scales we have used a Gaussian filter to reduce foreground contamination. The size of the independent sky regions was adapted to the multipole range to ensure sufficient spatial localization at the required resolution. We used a minimum of 12 regions at low resolution and a maximum of 3072 regions at high resolution.

4.1.2. NILC

In the multi-component extensions of NILC (Delabrouille et al. 2009; Remazeilles et al. 2011), initially developed to extract the CMB, the weights for component separation (i.e., covariances) are computed independently in domains of a needlet decomposition (in the spherical wavelet frame). The needlet decomposition provides localization of the ILC filters both in pixel and in multipole space, allowing us to deal with local contamination conditions varying both in position and in scale. We imposed constraints to remove the CMB contamination and preserve the tSZ effect. To avoid strong foreground effects, the Galactic plane was masked before applying NILC to the Planck frequency maps.

In both methods, we mask the brightest regions in the Planck 857 GHz channel map, corresponding to about 33% of the sky. We use the HFI channel maps from 100 to 857 GHz that are convolved to a common resolution of 10 \( \arcmin \). The 857 GHz map is mainly exploited in the internal linear combination as a template to remove the residual dust emission on large angular scales. However, this induces significant CIB residuals in the tSZ map on small scales. To avoid this contamination, while enabling efficient removal of the diffuse thermal dust emission at large angular scales, we use the 857 GHz channel only for \( \ell < 300 \).

4.2. Reconstructed Compton parameter \( y \) map

Figure [1] shows the reconstructed Planck all-sky Compton parameter map for NILC (top panel) and MILCA (bottom panel). For display purposes, the maps are filtered using the procedure described in Sect. [6]. Clusters appear as positive sources: the Coma cluster and Virgo supercluster are clearly visible near the north Galactic pole. As mentioned above, the Galactic plane is masked in both maps, leaving 67% of the sky. Other weaker and more compact clusters are visible in the zoomed region of the Southern cap, shown in the bottom panel of Fig. [2]. Strong Galactic and extragalactic radio sources show up as negative bright spots on the maps and were masked prior to any scientific analysis, as discussed below in Sect. [3]. Residual Galactic contamination is also visible around the edges of the masked area; extra masking was performed to avoid this highly contaminated area. The apparent difference of contrast observed between the NILC and MILCA maps comes from differences in the instru-
Fig. 1. Reconstructed Planck all-sky Compton parameter maps for NILC (top) and MILCA (bottom) in orthographic projections. The apparent difference in contrast observed between the NILC and MILCA maps comes from differences in the instrumental noise contribution and foreground contamination and from the differences in the filtering applied for display purpose to the original Compton parameter maps.
Planck Collaboration: Cosmology from the *Planck* all-sky Compton y parameter

**Fig. 2.** A small region of the reconstructed *Planck* all-sky Compton parameter maps for NILC (left) and MILCA (right) at intermediate Galactic latitudes in the southern sky.

mental noise and foreground contamination (the NILC map is slightly noisier but less affected by residual foreground emission than the MILCA map, as discussed in Sect. 5.2) and from the differences in the filtering applied for display purposes to the original Compton parameter maps, as discussed in Sect. 6.1.

In addition to the full Compton parameter maps, we also produce the so-called “FIRST” and “LAST” Compton parameter maps from the first and second halves of the survey rings (i.e., pointing periods). These maps are used for the power spectrum analysis in Sect. 5.

### 4.3. Point source contamination and masking

Point source contamination is an important issue for the cosmological interpretation of the *Planck* Compton parameter map. Radio sources will show up in the reconstructed tSZ maps as negative peaks, while infrared sources will show up as positive peaks, mimicking the cluster signal. To avoid contamination from these sources we introduce a point source mask (PSMASK, hereafter). This mask is the union of the individual frequency point-source masks discussed in Planck Collaboration XXVIII (2013). To test the reliability of this mask we have performed a search for negative sources in the Compton parameter maps using the MHW2 algorithm (López-Caniego et al. 2006). We found that all detected radio sources in the Compton parameter maps are masked by the PSMASK. For infrared sources, estimating the efficiency of the masking is hampered by the tSZ signal itself. The residual contamination from point sources is discussed in Sects. 5.2 and 6. It is also important to note that the PSMASK may also exclude some clusters of galaxies. This is particularly true in the case of clusters with strong central radio sources, such as the Perseus cluster (see Planck Collaboration XXIX 2013).

### 4.4. tSZ signal from resolved sources

As a first validation step of the Compton parameter maps we perform a blind search for the tSZ signal coming from resolved sources and compare it to the *Planck* catalogue of tSZ sources (Planck Collaboration XXIX 2013). The latter comprises 861 confirmed clusters out of 1227 cluster candidates and 54 CLASS1 highly reliable candidate clusters.

#### 4.4.1. Yields

Two lists of tSZ sources above a signal-to-noise ratio threshold of 4.5 are constructed from both MILCA and NILC all-sky Compton parameter maps outside a 33% Galactic mask. The point source detections are undertaken using two methods.

- **SMATCH**, in which sources are detected using the *SEXtractor* algorithm (Bertin & Arnouts 1996) over the whole sky divided into 504 patches. A single frequency matched filter (Melin et al. 2006a) is then applied to measure the tSZ flux density and signal-to-noise ratio using the Arnaud et al. (2010) pressure profile. Using this method, we detect 843 and 872 sources in MILCA and NILC, respectively.

- **MHWS**, in which tSZ sources are detected in the maps using IFCAMEX (MHW2, González-Nuevo et al. 2006; López-Caniego et al. 2006). The flux density and signal-to-noise ratio are then estimated using *SEXtractor* on 3.65° × 3.65° patches. We detect 1036 and 1740 sources in MILCA and NILC, respectively, with this method.

The difference between the yields of the two methods is understandable, as SMATCH is by construction dedicated to the search for tSZ sources and the precise measurement of their flux (including assumptions on the spatial distribution of the tSZ signal), whereas MHWS targets all types of compact source (includ
The critical density at the cluster redshift.

**Fig. 3.** Comparison of the measurements of $Y_{5850}$. **Left:** the values derived from the detection methods used to build the Planck catalogue of clusters ($Y_{5850,PSZ}$), plotted against those from the all-sky reconstructed MILCA $tSZ$ map ($Y_{5850,MAP}$). **Right:** the MILCA ($Y_{5850,MILCA}$) versus NILC ($Y_{5850,NILC}$) all-sky $tSZ$ effect maps. The equality relationship is marked as a dashed black line. A least-squares bisector method fit to the data lead to slopes of 1.09 ± 0.02 and 1.08 ± 0.02 for the MILCA and NILC Compton parameter maps, respectively.

**4.4.2. Photometry**

Of more importance than a comparison of yields is the comparison in terms of photometry. For all-sky map detections that are associated with clusters in the Planck SZ catalogue, the $SZ$ flux measurement from the all-sky maps correlates very well with the maximum likelihood value of the integrated Compton parameter, $Y_{586}$, provided by the dedicated SZ-detection methods in the Planck catalogue of $SZ$ sources (i.e., Milca, Mm, and PwS, Hernanz et al. 2002, Melin et al. 2006a, Carvalho et al. 2012, Planck Collaboration XXIX 2013). We apply XSpec to the FIRST and LAST $y$-maps obtained using NILC and MILCA. We consider the following map pairs: the MILCA FIRST and LAST (MILCA F/L); the NILC FIRST and LAST (NILC F/L); and the NILC FIRST and MILCA LAST (NILC-MILCA F/L), or equivalently the MILCA FIRST and MILCA LAST (MILCA-MILCA F/L). The noise is uncorrelated between the map pairs the resulting power spectrum is not biased and we preserve the variance.

To estimate the power spectrum of the $tSZ$ signal we use the XSpec method (Tristram et al. 2005) initially developed for the cross-correlation of independent detector maps. XSpec uses standard MASTER-like techniques (Hivon et al. 2002) to correct for the beam convolution and the pixelization, as well as the mode-coupling induced by masking foreground contaminated sky regions.

We apply XSpec to the FIRST and LAST $y$-maps obtained using NILC and MILCA. We consider the following map pairs: the MILCA FIRST and LAST (MILCA F/L); the NILC FIRST and LAST (NILC F/L); and the NILC FIRST and MILCA LAST (NILC-MILCA F/L), or equivalently the MILCA FIRST and NILC LAST (MILCA-NILC F/L). The noise is uncorrelated between the map pairs the resulting power spectrum is not biased and we preserve the variance.
We first identify the dominant foregrounds in the reconstructed Compton parameter maps. To do so, we apply to the FFP6 simulated data the linear combination weights of NILC and MILCA derived from the real data. In this way we have constructed maps of the expected foreground contamination in the final Compton parameter maps.

Figure 4 shows the angular power spectra for these reconstructed foreground contamination maps. We use the PSMASK and a conservative common Galactic mask that leaves 50% of the sky. The Galactic mask is constructed by removing the 50% brightest regions of the sky in the 857 GHz intensity map, as detailed below in Sect. 5.2.1. We show the diffuse Galactic contamination (blue), the clustered CIB contamination (green), and point source contamination (cyan). We consider here the foreground contamination in the cross-power spectra of the NILC F/L (dotted lines) and NILC-MILCA F/L maps (solid lines).

The tSZ power spectrum for the FFP6 simulations is plotted in red. For illustration we also show the Planck instrumental noise auto-power spectrum (dashed black line) in the MILCA Compton parameter map. We clearly observe that, as expected, the diffuse Galactic emission (mainly thermal dust), dominates the foreground contribution at low multipoles. For large multipoles the clustered CIB and point source contributions dominate the power spectrum. However, it is important to notice that the tSZ signal dominates the angular power spectrum in the multipole range 100 < ℓ < 800. We also note that foreground contamination differs depending on the reconstruction method, and we find that MILCA is more affected by foreground contamination. However, we also find that at large angular scales the diffuse Galactic dust contamination is significantly lower in the NILC-MILCA F/L cross-power spectrum than in the NILC F/L cross-power spectrum. This indicates that the residual dust contamination is not 100% correlated between the reconstructed MILCA and NILC Compton parameter maps. In contrast, the clustered CIB and point source contamination levels are similar for the two cross-power spectra at high multipoles, indicating that the residual contamination is essentially 100% correlated between the MILCA and NILC maps.

5.2. Foreground contamination

The challenge in computing the tSZ power spectrum is to estimate and minimize foreground contamination. We do not intend here to provide a detailed foreground analysis, but rather to identify the main foreground contaminants at different multipoles.

In the following, all the spectra will use a common multipole binning scheme, which was defined in order to minimize the correlation between adjacent bins at low multipoles and to increase the signal-to-noise at high multipole values. Error bars in the spectrum are computed analytically from the auto-power and cross-power spectra of the pairs of maps, as described in Tristram et al. (2005). All of our Compton parameter maps assume a circular Gaussian beam of 10' FWHM. The additional filtering at large angular scales in the MILCA Compton parameter maps is also accounted for and deconvolved.

5.2.1. Low-multipole contribution

The diffuse Galactic foreground contribution can be significantly reduced by choosing a more aggressive Galactic mask. Assuming that at large angular scales the Compton parameter maps are mainly affected by diffuse Galactic dust emission, we have tested several Galactic masks by imposing flux cuts on the Planck 857 GHz channel intensity map. In particular we investigated masking out 30%, 40%, 50%, 60%, and 70% of the sky. The edges of these masks have been apodized to limit ringing effects on the reconstruction of the angular power spectrum. Figure 5 presents the angular cross-power spectrum of the reconstructed NILC F/L Compton parameter maps for some of these Galactic masks: 30% (cyan); 40% (black); 50% (red); 60% (green); 70% (blue); and the PSMASK. We find that when masking 40% or more of the sky the tSZ angular power spectrum does not change significantly. That is why, conservatively, we select the 50% mask (GALMASK50 hereafter), which will be used in the remainder of our analysis.

We checked if the foreground contribution in the reconstructed Planck Compton parameter maps also depends on the reconstruction method. From the analysis of the FFP6 simulations we have found that the contribution from foregrounds in the NILC and MILCA Compton parameter maps is not the same, and it is not fully correlated. Similar results are found for the
the cross-correlation of the NILC amplitude than the NILC maps. We also find that the NILC parameter maps with respect to the dust contamination in the original maps. The cross-correlation coefficients that relate the cross-power spectra to the auto-power spectra. Following Planck Collaboration XXX (2013) we consider 5% global uncertainties on those coefficients. We use the Béthermin et al. (2012) model to compute the star-forming dusty galaxy contribution. Finally, we use the Tucci et al. (2011) model, fitted to the Planck ERCSC (Planck Collaboration Int. VII 2013), for extragalactic radio sources. Notice that these models are also used for the study of the clustered CIB with Planck (Planck Collaboration XXX 2013).

We now estimate the residual power spectrum in the y-map after component separation. We apply the MILCA or NILC weights to Gaussian-realization maps drawn using the cross- and auto-spectra of each component at the six Planck HFI frequencies. The residual power spectrum in the y-map can also be estimated in the spherical harmonic domain, as detailed in Appendix A. We have tested the consistency between the two approaches and we give here results for a map-based estimate using a total of 50 all-sky simulations for each of the foreground components. Specific simulations, varying the foreground models, were also performed to propagate the 5% global uncertainties of the model-coefficients (which include the overall uncertainties in the CIB modelling) into the estimated residual power spectrum. We find a 50% uncertainty in the amplitude of each residual spectrum (clustered CIB, star-forming dusty galaxies, and radio sources) in the y-map.

Figure 7 shows the NILC F/L cross-power spectrum before (black points) and after (red points) foreground correction, compared to the power spectra of the physically motivated foreground models. Specifically, we show: clustered CIB (green line); infrared sources (cyan line); and radio sources (blue line). The statistical (thick line) and total (statistical plus foreground, thin line), uncertainties are also shown. Additionally, we show the best-fit tSZ power spectrum model presented in Sect. 7.1 as a solid red line.

Planck data. Figure 6 shows the cross-power spectra between the MILCA F/L maps (black), the NILC F/L maps (red), and the NILC-MILCA F/L maps (blue), as a function of ℓ. We observe that the MILCA F/L cross-power spectrum shows a larger amplitude than the NILC F/L cross-power spectrum. This is most probably due to a larger foreground contamination in the MILCA Compton parameter map.

In addition, we find that the NILC-MILCA F/L cross-power spectrum shows the lowest amplitude at low multipoles (ℓ < 100). This is due to a reduction of the dust contamination in the cross-correlation of the NILC and MILCA Compton parameter maps with respect to the dust contamination in the original maps. We also find that the NILC-MILCA F/L lies between the MILCA F/L and NILC F-L cross-power spectra at high multipoles. This can be explained by the differences in the clustered CIB contamination in the MILCA and NILC Compton parameter maps. An accurate model of the clustered CIB power spectrum is available. However, this is not the case for the dust contamination power spectrum, and thus we restrict the power spectrum analysis presented in Sect. 7.1 to ℓ > 60.

Hereafter, we will consider the NILC F/L cross-power spectrum as a baseline for cosmological analysis, with the NILC-MILCA F/L cross-power spectrum being used to cross-check the results.

5.2.2. High-multipole contribution

The high-ℓ contamination from clustered CIB and point sources affects the measurement of the tSZ spectrum and its cosmological interpretation. Realistic models fitted to the Planck data are thus needed. We take advantage of the capability of Planck to measure and constrain these foreground emissions and use the outputs of Planck Collaboration XVIII (2011) and Planck Collaboration XXX (2013) for the clustered CIB modelling. For the six Planck HFI frequencies considered in this paper, the clustered CIB model consists of six auto-power spectra and 24 cross-power spectra. For frequencies above 217 GHz, these spectra are fitted in Planck Collaboration XXX (2013) to the measured CIB, consistently with Planck Collaboration XVIII (2011). The model is extrapolated at 100 and 143 GHz following Béthermin et al. (2012) and Planck Collaboration XVIII (2011). The uncertainties in the clustered-CIB model are mainly due to the cross-correlation coefficients that relate the cross-power spectra to the auto-power spectra. Following Planck Collaboration XXX (2013) we consider 5% global uncertainties on those coefficients.

We use the Béthermin et al. (2012) model to compute the star-forming dusty galaxy contribution. Finally, we use the Tucci et al. (2011) model, fitted to the Planck ERCSC (Planck Collaboration Int. VII 2013), for extragalactic radio sources. Notice that these models are also used for the study of the clustered CIB with Planck (Planck Collaboration XXX 2013).

Figure 7 shows the NILC F/L cross-power spectrum before (black points) and after (red points) foreground correction, using the refined foreground models presented above. We also show the clustered CIB (green), infrared source (cyan), and radio source (blue) power spectrum contributions.
5.3. Contribution of resolved clusters to the tSZ power spectrum

We simulate the expected Compton parameter map for the detected and confirmed clusters of galaxies in the Planck catalogue (Planck Collaboration XXIX 2013) from their measured integrated Compton parameter, $y_{5R500}$. The orange solid line in Fig. 8 shows the power spectrum of this simulated map. Figure 8 also shows the cross-power spectrum of the NILC F/L maps after masking the confirmed clusters from the PSZ catalogue. The green curve corresponds to the difference of the two cross-power spectra, with and without masking the clusters. It is in good agreement with the modelled power spectrum of the confirmed clusters of galaxies. We also compute the cross-power spectrum of the simulated cluster map and the Planck reconstructed Compton parameter NILC map. This is shown in blue in the figure. Here again, the signal is consistent with the expected power spectrum of the confirmed Planck clusters of galaxies.

These results show that a significant fraction of the signal in the reconstructed Planck Compton parameter maps is due to the tSZ effect of detected and confirmed clusters of galaxies, verifying the SZ nature of the signal. In addition, by comparing the tSZ power spectrum from the resolved clusters with the marginalized tSZ power spectrum presented in Sect. 7, we deduce that the measured tSZ spectrum includes an additional tSZ contribution from unresolved clusters and diffuse hot gas.

6. Analysis of high-order statistics

The power spectrum analysis presented above only provides information on the 2-point statistics of the Compton parameter distribution over the sky. An extended characterization of the field can be performed by studying the higher-order moments in the 1D PDF of the map, or by measuring 3-point statistics, i.e., the bispectrum.
behaves better than the more traditionally used Wiener filter, as it is less affected by point-source ringing. Following this procedure, the 1D PDF of the filtered Compton parameter map, $P(y)$, is computed from the histogram of the pixels.

Figure 9 shows the 1D PDF for the FFP6 simulation maps combined using the weights of the NILC linear combination of the real data. We present in red the 1D PDF of the tSZ effect, which is clearly asymmetric, with a positive tail as expected. Moreover, the asymptotic slope of this red curve at high values of $y$ scales almost as $P(y) \propto y^{-5.5}$, implying that the underlying source counts should scale in the same way (i.e., $dn/dy \propto y^{-5.5}$). This is the predicted scaling behaviour for clusters (e.g., de Luca et al. 1995; Rubi˜no-Martín & Sunyaev 2003), and indeed, it is the scaling that we find in the actual number counts of clusters in the simulation used. Similarly, the 1D PDF for radio sources (black) is also asymmetric, but with a negative tail. By contrast, the clustered CIB (blue) and diffuse Galactic emission (cyan) contributions: a Gaussian central part that exceeds slightly the expected distribution if fluctuations were only Gaussian central part that exceeds slightly the expected distribution if fluctuations were only

Moreover, the asymptotic slope of this red curve at high values of $y$ scales almost as $P(y) \propto y^{-5.5}$, implying that the underlying source counts should scale in the same way (i.e., $dn/dy \propto y^{-5.5}$). This is the predicted scaling behaviour for clusters (e.g., de Luca et al. 1995; Rubi˜no-Martín & Sunyaev 2003), and indeed, it is the scaling that we find in the actual number counts of clusters in the simulation used. Similarly, the 1D PDF for radio sources (black) is also asymmetric, but with a negative tail. By contrast, the clustered CIB (blue) and diffuse Galactic emission (cyan) contributions: a Gaussian central part that exceeds slightly the expected distribution if fluctuations were only Gaussian.

\[ \langle y \rangle \equiv \int y P(y)dy = -\frac{\Delta}{\sqrt{3}}, \quad \langle y^2 \rangle = \frac{\Delta}{4}, \quad \langle y^3 \rangle = -\frac{\sqrt{3}}{5} \Delta. \]

with $P(y) \propto y^{-5.5}$, implying that the underlying source counts should scale in the same way (i.e., $dn/dy \propto y^{-5.5}$). This is the predicted scaling behaviour for clusters (e.g., de Luca et al. 1995; Rubi˜no-Martín & Sunyaev 2003), and indeed, it is the scaling that we find in the actual number counts of clusters in the simulation used. Similarly, the 1D PDF for radio sources (black) is also asymmetric, but with a negative tail. By contrast, the clustered CIB (blue) and diffuse Galactic emission (cyan) contributions: a Gaussian central part that exceeds slightly the expected distribution if fluctuations were only Gaussian.

\[ \langle y \rangle \equiv \int y P(y)dy = -\frac{\Delta}{\sqrt{3}}, \quad \langle y^2 \rangle = \frac{\Delta}{4}, \quad \langle y^3 \rangle = -\frac{\sqrt{3}}{5} \Delta. \]

shows the results for the NILC and MILCA maps. The different filtering function derived for the NILC and MILCA $y$-maps prevents a direct one-to-one comparison of the skewness values. However, the comparison of each map with the FFP6 simulations of the tSZ component and of the sum of all components clearly shows that the contribution of foregrounds is minor in both maps, and suggests that the measured skewness is mainly dominated by the tSZ signal, as one would expect from Figs. 9 and 10. By comparing the measured and model skewness, we present constraints on $\sigma_8$ in Sect. 7.2.

6.2. Bispectrum

Since the SZ signal is non-Gaussian, significant statistical information is contained in the bispectrum, complementary to the power spectrum (Rubi˜no-Martín & Sunyaev 2003; Bhattacharya et al. 2012). We therefore compute the bispectrum of the NILC and MILCA reconstructed Compton parameter maps. The results presented here use the binned bispectrum estimator described in Bucher et al. (2010) and Lacasa et al. (2012), which is also used for the Planck primordial non-Gaussianity analysis (Planck Collaboration XXIV 2013). We mask the maps with the combined PSMASK and GALMASK50, remove the best-fit monopole and dipole outside the mask, and degrade the resolution to $N_{side} = 1024$ to reduce computing time. We use a multipole bin size $\Delta l = 64$ and a maximum multipole $l_{max} = 2048$ for the analysis. To correct for the bias introduced by masking, we have produced non-Gaussian simulations with a tSZ-like bispectrum and we have convolved the simulated maps with a Gaussian beam of 10' FWHM. We compute the bispectrum of the simulated full-sky and masked maps and measure the average ratio between the two. This ratio is used to correct the measured bispectra and flag unreliable $(\ell_1, \ell_2, \ell_3)$ configurations, for which mask effects are too large to be corrected.

We checked that foreground residuals do not significantly affect the recovered tSZ bispectrum by using the FFP6 simulations described previously. In the case of the NILC reconstructed map (more affected by foregrounds), for example, Fig. 11 shows the tSZ bispectrum as well as the (absolute value of the) bispectra of the different foreground residuals. This is shown for some some special configurations, namely equilateral $(\ell, \ell, \ell)$, orthogonal isosceles $(\ell, \ell, \sqrt{2}\ell)$, flat isosceles $(\ell, \ell, 2\ell)$ and squeezed $(\ell_{min}, \ell, \ell)$. The foreground residuals yield negligible bispectra, at least one order of magnitude smaller than the tSZ bispectrum over the multipoles of interest.

In Fig. 12 we compare the tSZ bispectrum measured on Planck data, with the tSZ bispectrum of the FFP6 simulation and with the bispectrum of the maps of detected clusters in the Planck catalogue presented above. Clusters from the Planck catalogue contribute an important fraction of the measured bispectrum, at least 30% on large angular scales and more on smaller angular scales; the bispectrum therefore also probes the unresolved tSZ signal, as was the case for the power spectrum. On large angular scales this may be the signature of the clustering of less massive dark matter halos inside the large-scale structures.

7. Cosmological Interpretation

7.1. Power spectrum analysis

As a measure of structure growth, the tSZ power spectrum can provide independent constraints on cosmological parameters and potentially improve their precision. As shown by Komatsu & Seljak (2002), the power spectrum of the tSZ effect is highly sensitive to the normalization of the matter power spectrum, commonly parameterized by the rms of the \(z = 0\) mass distribution on 8 \(h^{-1}\) Mpc scales, \(\sigma_8\), and to the total amount of matter \(\Omega_m\). We expect the tSZ power spectrum to also be sensitive to other cosmological parameters, e.g., \(\Omega_b\), \(H_0\), and \(n_s\). For reasonable external priors on those parameters, however, the variations are expected to be negligible with respect to those introduced by changes in \(\Omega_m\) and \(\sigma_8\) and are not considered here. Finally, we also expect the tSZ power spectrum amplitude to be sensitive to the "mass bias", \(b\). A full joint analysis of cosmological parameters and mass bias is not possible with the current data and so we have chosen here to fix the mass bias to \(b = 0.2\) following results in the companion Planck paper on cosmological constraints from Planck SZ cluster counts (Planck Collaboration XX [2013]). Note that final cosmological constraints depend on this choice.

Cosmological constraints are obtained from a fit of the NILC F/L cross-power spectrum, for the 50% mask, assuming a three-component model: tSZ; clustered CIB; and radio and infrared point sources. For \(\ell > 60\), we can reasonably neglect the Galactic dust contamination. For \(\ell > 1411\) the total signal in the tSZ map is dominated by noise. We thus restrict our analysis to the multipole range \(60 < \ell < 1411\). The measured power spectrum, \(C_{\ell}^m\), is modelled as:

\[
C_{\ell}^m = C_{\ell}^{tSZ}(\Omega_m, \sigma_8) + A_{\text{CIB}} C_{\ell}^{\text{CIB}} + A_{\text{PS}} (C_{\ell}^{\text{IR}} + C_{\ell}^{\text{Rad}}).
\]
compute the tSZ power spectrum at the largest angular scales. It is consistent with the tSZ spectrum presented in Efstathiou & Migliaccio (2012), which was used as a template in the CMB cosmological analysis in Planck Collaboration XV (2013) and Planck Collaboration XVII (2013).

Foreground contamination is modelled following Sect. 5.2.2. As discussed there, the main uncertainties in the residual power spectrum translate into up to 50% uncertainty in the clustered CIB and point source amplitudes. We thus allow for a variation of the normalization amplitudes for the clustered CIB, ACIB, and for the point sources, APS, with Gaussian priors centred on 1 with standard deviation 0.5.

We have not considered explicitly the expected correlation between the tSZ effect and the CIB. However, using the formalism in Addison et al. (2012), we have performed simulations of the expected effect and find that to a reasonable level of approximation the shape of the tSZ and clustered CIB cross-power spectrum is very similar to that of the clustered CIB power spectrum. Therefore, in our simplified modelling, the clustered CIB normalization factor, ACIB, also accounts for this component.

We assume a Gaussian approximation for the likelihood function. Best-fit values and uncertainties are obtained using an adapted version of the CosmoMC algorithm (Lewis & Bridle 2002). Only $\sigma_8$ and $\Omega_m$ are allowed to vary here. All other cosmological parameters are fixed to their best-fit values as obtained in Table 2 of Planck Collaboration XVI (2013). The normalization amplitudes, ACIB and APS, considered as nuisance parameters, are allowed to vary between 0 and 3. For the range of multipoles considered here, the tSZ angular power spectrum varies like $C_\ell \propto \sigma_8^{4} (\Omega_m/0.28)^{3/8}$. The results are thus presented in terms of this parameter combination.

Figure 13 presents the 2D and 1D likelihood distributions for the combination of cosmological parameters $\sigma_8(\Omega_m/0.28)^{0.40}$, and for the foreground parameters ACIB and APS. We show the 68.3% and 95.4% C.L. contours (in orange).

We also show as a blue solid line the best-fit tSZ power spectrum obtained from the analysis of cluster number counts (Planck Collaboration XX 2013). The tSZ power spectrum template used in the CMB cosmological analysis (Planck Collaboration XV 2013; Planck Collaboration XVI 2013) is presented as a green solid line. For comparison, we also show the SPT (Reichardt et al. 2012, orange diamond) and ACT (Sievers et al. 2013, cyan diamond) constraints on the tSZ power spectrum at $\ell = 3000$.

In Fig. 16, we compare the Planck tSZ measurements of the power spectrum to a set of predicted spectra. We consider the predictions derived from hydrodynamical simulations (Battaglia et al. 2010; Battaglia et al. 2012, brown), from $N$-body simulations plus semi-analytical models (Trac et al. 2011, purple and cyan) and from analytical calculations (Shaw et al. 2010, black; Komatsu & Seljak 2002, orange). These models were computed originally for the set of cosmological parameters in Hinshaw et al. (2012) with $\sigma_8 = 0.8$ and have been rescaled in amplitude to our best-fit value for $\sigma_8^{18}$.$\Omega_m^{0.2}$. We note that there is some dispersion in the predicted amplitudes and shapes of the tSZ power spectrum. These differences reflect the range of methodologies and assumptions used both in the physical properties of clusters and in the technical details of the computation. The latter includes differences in the redshift ranges and also in the mass intervals probed by the limited sizes of the simulation boxes of the hydrodynamical simulations. Analytical predictions are also sensitive to the model ingredients, such as the mass function, mass bias and scaling relations adopted.

We see from Fig. 16 that most of the models presented above (the tSZ template for CMB analyses, plus the Battaglia et al. 2012, Shaw et al. 2010 and TBO2 models) provide reasonable fits to the data, while the others (TBO1 and Komatsu & Seljak 2002, orange) do not.

The measured tSZ power spectrum is in remarkable agreement with the tSZ power spectrum (blue solid line) computed using the cluster count best-fit parameters (Planck Collaboration XX 2013). We also show in Fig. 15 (green line) the tSZ template used in the Planck CMB analysis (Planck Collaboration XVI 2013). This template is renormalized by a simple scaling factor using the best-fit $\sigma_8(\Omega_m/0.28)^{0.40}$. The difference in shapes of the two spectra is due to the different assumptions used for the scaling relation between SZ signal and mass (see, Efstathiou & Migliaccio 2012). We also show the SPT (Reichardt et al. 2012, orange diamond) and ACT (Sievers et al. 2013, cyan diamond) constraints on the tSZ power spectrum at $\ell = 3000$, which are consistent with our best-fit model within $\pm 2\sigma$ and illustrate that the tSZ spectrum starts to turn over at higher $\ell$.

In Fig. 16, we compare the Planck tSZ measurements of the power spectrum to a set of predicted spectra. We consider the predictions derived from hydrodynamical simulations (Battaglia et al. 2010; Battaglia et al. 2012, brown), from $N$-body simulations plus semi-analytical models (Trac et al. 2011, purple and cyan) and from analytical calculations (Shaw et al. 2010, black; Komatsu & Seljak 2002, orange). These models were computed originally for the set of cosmological parameters in Hinshaw et al. not consider in the following the dependency of the bispectrum and the unnormalized skewness on other cosmological parameters, since all such dependencies are expected to be significantly lower than for $\sigma_8$ (Bhattacharya et al. 2012).

We derive constraints on $\sigma_8$ by comparing the measured unnormalized skewness and bispectrum amplitudes with those obtained from simulations of the tSZ effect. This approach is strongly limited by systematic uncertainties and the details of the theoretical modelling (see Hill & Sherwin 2013).

From the measured unnormalized skewness of the filtered MILCA and NILC Compton parameter maps discussed in Sect. 6.1 and by comparing them to the value measured in the FFP6 simulations we can derive constraints on $\sigma_8$. Uncertainties due to foreground contamination are computed using the FFP6 simulations and are accounted for in the final error bars. The tSZ component of the FFP6 simulations was obtained from a hybrid simulation including a hydrodynamic component for $z < 0.3$ plus extra individual clusters at $z > 0.3$, and with $\sigma_8 = 0.789$. Using these simulations we obtain $\sigma_8 = 0.775$ for NILC and $\sigma_8 = 0.783$ for MILCA. Combining the two results and considering model and foreground uncertainties we obtain $\sigma_8 = 0.779 \pm 0.015$ (68% C.L.). Notice that the uncertainties are mainly dominated by foreground contamination. Model uncertainties here only account for the expected dependence of the unnormalized skewness upon $\sigma_8$, as shown in Sect. 5. We have neglected, as was also the case in Wilson et al. (2012), the dependence on other cosmological parameters. We have also not considered any uncertainties coming from the combination of the hydrodynamical and individual cluster simulations. Because of these constraints, our error bars might be underestimated.

The comparison of the measured bispectrum obtained from the Planck Compton parameter maps with the FFP6 simulation tSZ bispectrum shows an offset of about a factor of two on small angular scales, $300 < \ell < 700$, which we attribute to the differences in cosmological parameters. Using the scaling of the bispectrum with $\sigma_8$, its uncertainty, as well as the uncertainty on the bispectra ratio, we obtain $\sigma_8 = 0.74 \pm 0.04$ (68% C.L.). As was the case for the unnormalized skewness, we neglected here the dependence on other cosmological parameters and the uncertainties in the FFP6 simulations. Thus the error bar might again be somewhat underestimated. However, we expect those additional uncertainties to be smaller than the error bars we quote.

8. Conclusion

Because of its wide frequency coverage from 30 to 857 GHz, the Planck satellite mission is particularly well suited for the measurement of the thermal Sunyaev-Zeldovich effect. Working with the Planck frequency channel maps from 100 to 857 GHz, we have reconstructed the tSZ signal over the full sky using tailored component separation methods. In this paper, we have analysed the first all-sky tSZ map quantified in terms of the Compton parameter and with an angular resolution of 10'.

We have characterized the reconstructed Planck all-sky Compton parameter map in terms of blind detection of tSZ sources, and the angular power spectrum and higher order statistics via the study of its 1D PDF and bispectrum. In all cases we have identified, characterized and carefully modelled the contamination by foreground emission. This is mainly due to diffuse Galactic thermal dust emission at large angular scales ($\ell \lesssim 60$), and clustered CIB and Poisson-distributed radio and infrared sources at smaller angular scales (dominating at $\ell \gtrsim 500$). Diffuse Galactic thermal dust emission is tackled via a conservative masking of the brightest 50% of the sky in the Planck.
857 GHz channel map. The CIB and point-source contamination are modelled in a way which is consistent with the findings of [Planck Collaboration XVIII (2011) and Planck Collaboration XXX (2013)].

We have produced the first measurement of the SZ power spectrum on large angular scales, ranging over 0.17° ≤ θ ≤ 3.0°. In this range, the tSZ power spectrum is almost insensitive to the physics of cluster cores. The detected tSZ signal likely arises from the contribution of warm and hot diffuse gas distributed within groups and clusters, sampling the whole halo mass function, as well as within the larger-scale filamentary structures.

We have modelled the tSZ power spectrum via a halo-model analytical approach, in order to investigate its dependence on σ8 and Ωm and to test it against the measured Planck tSZ power spectrum. Moreover, we performed an analysis of the 1D PDF and bispectrum of the Planck y-map to infer independent constraints. We find, in the present framework, that the best-fit normalisation parameter σ8 from the three independent analysis ranges between (0.74±0.06) and (0.78±0.02) at 68% C.L. for the high-order statistics and power spectrum analyses, respectively. These values are lower than those derived from analysis of primary CMB anisotropies [Planck Collaboration XVI (2013)].

More refined analysis and modelling will be needed to understand this difference, since the tension may have several possible origins. Some of the difference may be due to specific choices in the tSZ modelling, e.g., the mass bias (see Planck Collaboration XXI [2013] for a detailed discussion on its effect on cluster counts). Other differences could arise from the foreground modelling, in particular at high frequencies, above 217 GHz.

The observed consistency between constraints derived from the cluster number counts in Planck Collaboration XX (2013) and from the present work provides a coherent view of the gas content in halos and in larger-scale structures. As such, this Planck tSZ measurement constitutes the first step towards building a comprehensive understanding of the integrated tSZ effect due to cosmic structure on all scales and at all density contrasts.

Appendix A: Foreground contamination in the final tSZ power spectrum

Since we are using modified Internal Linear Combination methods to estimate the final Planck Compton parameter we can write it as

\[ \hat{y}(\theta, \phi) = \sum_v \sum_v W_v^b(\theta, \phi) \left( F^b(\theta, \phi) + M_v(\theta, \phi) \right), \]  

(A.1)

where \( M_v(\theta, \phi) \) is the Planck map for frequency channel \( v \), \( F^b(\theta, \phi) \) is a circular filtering function for the multipole interval \( b \), and \( W_v^b(\theta, \phi) \) are the weights of the internal linear combination into that multipole range. Decomposing \( \hat{y}(\theta, \phi) \) in spherical harmonics we obtain

\[ \hat{y}_{l,m} = \sum_v \sum_b W_v^b \ell_{m} \ell'_{m'} F_v^b(\theta, \phi) M_{l,m}, \]  

(A.2)

Then using spherical harmonic convolution properties (see for example Tristram et al.[2005]), and assuming overlap in the multipole range selected by the filter functions, \( F_v^b(\theta, \phi) \), then the power spectrum is given by

\[ C_{l}^{y y} = \sum_b W_v^b W_v' b^{'b} \left\{ F_v^b F_v'^b F_v^b F_v'^b M_{l,m} M_{l',m'} \right\}, \]  

(A.3)

where \( M_{l,m} M_{l',m'} \) represents the mode-coupling matrix associated with \( W_v^b \times W_v'^b \).

For each Planck channel the sky signal can be expressed as the sum of multiple components, including CMB, tSZ, diffuse Galactic emission, radio and IR point sources, and clustered CIB, such that the Planck Compton parameter is given by

\[ \hat{y} = y + y_{\text{CMB}} + \sum_c y_c', \]  

(A.4)

where \( c \) sums over the different foreground contributions. By construction \( y_{\text{CMB}} = 0 \) and thus, assuming no correlation between foreground components, the estimated tSZ spectrum can be expressed as

\[ C_{l}^{y y} = C_{l}^{y y}_{\text{SZ}} + \sum_c C_{l}^{y y}_{c'}'. \]  

(A.5)

Using Eq. (A.1) we write

\[ y'(\theta, \phi) = \sum_v \sum_b W_v^b(\theta, \phi) \left( F^b(\theta, \phi) + M_v(\theta, \phi) \right), \]  

(A.6)

and thus, using Eq. (A.3), we have

\[ C_{l}^{y y'} = \sum_b W_v^b W_v'^b \left\{ F_v^b F_v'^b F_v^b F_v'^b M_{l,m} M_{l',m'} \right\}. \]  

(A.7)

The latter expression can be simplified assuming a common spatial distribution of the foreground emission across frequencies and a well defined spectral energy density, \( f_c' \), so that it reads

\[ C_{l}^{y y'} = \sum_b \sum_{l} \sum_{l'} W_v^b W_v'^b \left\{ F_v^b F_v'^b f_c' f_c'^b M_{l,m} M_{l',m'} \right\}. \]  

(A.8)

Let us now look at the cross-correlation between the estimated Compton parameter map and a particular sky component at one of the observation frequencies \( M_v^c(\theta, \phi) = \sum_{l,m} T_{c,l,m} Y_{l,m}(\theta, \phi) \). We define the cross-power spectrum as

\[ C_{l}^{y y'}(\nu) = \frac{1}{2l + 1} \sum_{l,m} \hat{y}_{l,m} M_{c,l,m}^{y y'}(\nu) \]  

(A.9)

and the statistical expectation of this quantity reads

\[ \langle C_{l}^{y y'}(\nu) \rangle \rangle = \frac{1}{2l + 1} \sum_{n=x-l}^{x+l} \sum_{n'=x-l'}^{x+l'} W_{n}^{1/2, 1/2} W_{n'}^{1/2, 1/2} F_{n}^{1/2} \left\{ M_{c,l,m}^{y y'}(\nu) \right\} \]  

(A.10)

\[ = \frac{1}{2l + 1} \sum_{n=x-l}^{x+l} \sum_{n'=x-l'}^{x+l'} W_{n}^{1/2, 1/2} W_{n'}^{1/2, 1/2} C_{n n'}^{y y'}(\nu) \]  

(A.11)

\[ = \frac{1}{2l + 1} \sum_{n=x-l}^{x+l} \sum_{n'=x-l'}^{x+l'} W_{n}^{1/2, 1/2} W_{n'}^{1/2, 1/2} \delta_{n n'} \]  

(A.12)

Assuming that we have a measure of \( C_{n n'}^{y y'} \) and a way to derive \( W_{n}^{1/2, 1/2} W_{n'}^{1/2, 1/2} F_{n}^{1/2} \), we can compare the measured cross-correlation \( \hat{y} \times c \) to its theoretical expectation and thus have a consistency check on each component’s contribution to \( \hat{y} \).

41 Dpto. Astrofísica, Universidad de La Laguna (ULL), E-38206 La Laguna, Tenerife, Spain
42 European Southern Observatory, ESO Vitacura, Alonso de Cordova 3107, Vitacura, Casilla 19001, Santiago, Chile
43 European Space Agency, ESAC, Planck Science Office, Camino bajo del Castillo, s/n, Urbanización Villarfranca del Castillo, Villanueva de la Cañada, Madrid, Spain
44 European Space Agency, ESTEC, Keplerlaan 1, 2201 AZ Noordwijk, The Netherlands
45 Finnish Centre for Astronomy with ESO (FINCA), University of Turku, Väisäläntie 20, FIN-21500, PIikkiö, Finland
46 Haverford College Astronomy Department, 370 Lancaster Avenue, Haverford, Pennsylvania, U.S.A.
47 Helsinki Institute of Physics, Gustaf Hällström katu 2, University of Helsinki, Helsinki, Finland
48 INAF - Osservatorio Astrofisico di Catania, Via S. Sofia 78, Catania, Italy
49 INAF - Osservatorio Astronomico di Padova, Vicolo dell'Osservatorio 5, Padova, Italy
50 INAF - Osservatorio Astronomico di Roma, via di Frascati 33, Monte Porzio Catone, Italy
51 INAF - Osservatorio Astronomico di Trieste, Via G.B. Tiepolo 11, Trieste, Italy
52 INAF Istituto di Radioastronomia, Via P. Gobetti 101, 40129 Bologna, Italy
53 INAF/IASF Bologna, Via Gobetti 101, Bologna, Italy
54 INAF/IASF Milano, Via E. Bassini 15, Milano, Italy
55 INFN, Sezione di Bologna, Via Irnerio 46, I-40126, Bologna, Italy
56 INFN, Sezione di Roma 1, Università di Roma Sapienza, Piazzale Aldo Moro 2, 00185, Roma, Italy
57 IPAG: Institut de Planétologie et d’Astrophysique de Grenoble, Université Joseph Fourier, Grenoble 1 / CNRS-INSU, UMR 5274, Grenoble, F-38041, France
58 IUCAA, Post Bag 4, Ganeshkhind, Pune University Campus, Pune 411 007, India
59 Imperial College London, Astrophysics group, Blackett Laboratory, Prince Consort Road, London, SW7 2AZ, U.K.
60 Infrared Processing and Analysis Center, California Institute of Technology, Pasadena, CA 91125, U.S.A.
61 Institut Néel, CNRS, Université Joseph Fourier Grenoble I, 25 rue des Martyrs, Grenoble, France
62 Institut Universitaire de France, 103, bd Saint-Michel, 75005, Paris, France
63 Institut d’Astrophysique Spatiale, CNRS (UMR8617) Université Paris-Sud 11, Bâtiment 121, Orsay, France
64 Institut d’Astrophysique de Paris, CNRS (UMR7095), 98 bis Boulevard Arago, F-75014, Paris, France
65 Institute for Space Sciences, Bucharest-Magurele, Romania
66 Institute of Astronomy and Astrophysics, Academia Sinica, Taipei, Taiwan
67 Institute of Theoretical Astrophysics, University of Cambridge, Madingley Road, Cambridge CB3 0HA, U.K.
68 Institute of Theoretical Astrophysics, University of Oslo, Blindern, Oslo, Norway
69 Instituto de Astrofisica de Canarias, C/Vía Láctea s/n, La Laguna, Tenerife, Spain
70 Instituto de Física de Cantabria (CSIC-Universidad de Cantabria), Avda. de los Castros s/n, Santander, Spain
71 Jet Propulsion Laboratory, California Institute of Technology, 4800 Oak Grove Drive, Pasadena, California, U.S.A.
72 Jodrell Bank Centre for Astrophysics, Alan Turing Building, School of Physics and Astronomy, The University of Manchester, Oxford Road, Manchester, M13 9PL, U.K.
73 Kavli Institute for Cosmology Cambridge, Madingley Road, Cambridge, CB3 0HA, U.K.
74 LAL, Université Paris-Sud, CNRS/IN2P3, Orsay, France
75 LERMA, CNRS, Observatoire de Paris, 61 Avenue de l’Observatoire, Paris, France
76 Laboratoire AIM, IRFU/Service d’Astrophysique - CEA/DSM - CNRS - Université Paris Diderot, Bât. 709, CEA-Saclay, F-91191 Gif-sur-Yvette Cedex, France
77 Laboratoire Traitement et Communication de l’Information, CNRS (UMR 5141) and Télécom ParisTech, 46 rue Barrault F-75634 Paris Cedex 13, France
78 Laboratoire de Physique Subatomique et de Cosmologie, Université Joseph Fourier Grenoble I, CNRS/IN2P3, Institut National Polytechnique de Grenoble, 53 rue des Martyrs, 38026 Grenoble cedex, France
79 Laboratoire de Physique Théorique, Université Paris-Sud 11 & CNRS, Bâtiment 210, 91405 Orsay, France
80 Lawrence Berkeley National Laboratory, Berkeley, California, U.S.A.
81 Max-Planck-Institut für Astrophysik, Karl-Schwarzschild-Str. 1, 85741 Garching, Germany
82 McGill Physics, Ernest Rutherford Physics Building, McGill University, 3600 university road, Montréal, QC, H3A 2T8, Canada
83 MilliLab, VTT Technical Research Centre of Finland, Tietotie 5, Espoo, Finland
84 Niels Bohr Institute, Blegdamsvej 17, Copenhagen, Denmark
85 Observational Cosmology, Mail Stop 367-17, California Institute of Technology, Pasadena, CA, 91125, U.S.A.
86 Optical Science Laboratory, University College London, Gower Street, London, U.K.
87 SB-ITP-LPPC, EPEL, CH-1015, Lausanne, Switzerland
88 SISSA, Astrophysics Sector, via Bonomea 265, 34138, Trieste, Italy
89 School of Physics and Astronomy, Cardiff University, Queens Buildings, The Parade, Cardiff, CF24 3AA, U.K.
90 School of Physics and Astronomy, University of Nottingham, Nottingham NG7 2RD, U.K.
91 Space Research Institute (IKI), Russian Academy of Sciences, Profsoyuznaya Str, 84/32, Moscow, 117997, Russia
92 Space Sciences Laboratory, University of California, Berkeley, California, U.S.A.
