The Dimeric Form of 1,3-Diaminoisoquinoline Derivative Rescued the Mis-splicing of Atp2a1 and Clcn1 Genes in Myotonic Dystrophy Type 1 Mouse Model

Jun Matsumoto,[a] Masayuki Nakamori,[b] Tatsumasa Okamoto,[a] Asako Murata,[a] Chikara Dohno,[a] and Kazuhiko Nakatani*[a]

Abstract: Expanded CUG repeat RNA in the dystrophia myotonica protein kinase (DMPK) gene causes myotonic dystrophy type 1 (DM1) and sequesters RNA processing proteins, such as the splicing factor muscleblind-like 1 protein (MBNL1). Sequestration of splicing factors results in the mis-splicing of some pre-mRNAs. Small molecules that rescue the mis-splicing in the DM1 cells have drawn attention as potential drugs to treat DM1. Herein we report a new molecule JM642 consisted of two 1,3-diaminoisoquinoline chromophores having an auxiliary aromatic unit at the C5 position. JM642 alternates the splicing pattern of the pre-mRNA of the Ldb3 gene in the DM1 cell model and Clcn1 and Atp2a1 genes in the DM1 mouse model. In vitro binding analysis by surface plasmon resonance (SPR) assay to the r(CUG) repeat and disruption of ribonuclear foci in the DM1 cell model suggested the binding of JM642 to the expanded r(CUG) repeat in vivo, eventually rescue the mis-splicing.

Molecules modulating the splicing pattern of genes in DM1 cells have drawn attention as potential drugs treating this devastating neurological disorder.[5–7] DM1 is an autosomal dominant neuromuscular disorder, characterized by myotonia (delayed relaxation of muscles after contraction), progressive weakness, cardiac conduction defects, and cognitive impairments. The aberrant expansion of the CTG repeat in the 3′ untranslated regions of the DMPK gene is the cause of the disease.[5–7] The transcript of the DMPK gene with the long CUG repeat sequesters the RNA-binding proteins, such as the splicing factor MBNL1 in the nucleus.[8, 9] As a consequence, several genes in DM1 cells showed different splicing patterns from those observed in the wild type cells.[10, 11] In the splicing of pre-mRNA of the LIM domain binding 3 (Ldb3) gene, exon 11 is excluded from mRNA by about 80% in the wild type, but exon 11-included mRNA is produced about 50% in DM1 cells.[10, 11] In the splicing of pre-mRNAs encoding muscle-specific chloride channel (Clcn1), the mRNA without exon 7a is dominant in wild type, whereas exon 7a-included mRNA is abundant in DM1 cells.[12] Similarly, splicing of pre-mRNA of the Atp2a1 gene coding sarcoplasmic reticulum calcium-ATPase 1 (SERCA1) produces mRNA containing exon 22 in the wild type cells, whereas mRNA without exon 22 predominates in DM1 cells.[14] Misregulated alternative splicing is a fundamental molecular feature of DM1, having good potential to function as biomarkers of severity and therapeutic response.[11]

These differences in the splicing patterns between the wild type and DM1 encouraged studies focused on the modulation of the splicing patterns. Besides prominent approaches using oligonucleotides,[15] several groups have reported small molecules binding to the CUG repeats and modulating the splicing pattern in DM1 cells.[16–29] We here report that the dimeric form of 1,3-diaminoisoquinoline derivative JM642 (Figure 1) rescued the mis-splicing in Ldb3 pre-mRNA in the DM1 cell model and Clcn1 and Atp2a1 pre-mRNAs in DM1 mouse model in a dose-dependent manner. SPR assay showed the binding of JM642 to the r(CUG) repeat-immobilized sensor surface, and JM642 led to the disruption of ribonuclear foci in DM1 cell model expressing r(CUG)10 repeats, demonstrating that JM642 would be a useful molecular tool for the deeper understanding of the pathogenesis of DM1 and studies on the therapeutic potential of small molecules targeting DM1.

Figure 1. Chemical structures of JM608 and the dimeric form JM642.
We have reported different types of molecules that bind to r(CUG) repeat and modulate the alternative splicing in DM1 cells. After structure–activity studies on small molecules targeting the r(CUG) repeat, we revisited 1,3-diaminoisouquinoline derivatives with an additional aromatic unit at the C5 position and found a monomeric 1,3-diaminoisouquinoline ligand JM608 and its dimeric form JM642. (Figure 1) While the detail of structure–activity studies will be reported elsewhere, in brief, the substituent at the C5 position of the 1,3-diaminoisouquinoline chromophore showed a significant effect on the binding to the CUG repeat RNA. JM608 was synthesized by Suzuki–Miyaura cross-coupling\(^{34}\) of the 1-amino-5-bromo-3-chloroisoquinoline derivative 3 with a piperazine-substituted pyridinyl pinacol boronic ester 8 followed by Buchwald-Hartwig cross-coupling\(^{35}\) of the resulting 4 at the C3 position with the Boc-protected carbamate 9. (Scheme 1) Deprotection of all Boc groups in 5 furnished the synthesis of JM608. JM642 was obtained by coupling of 4 with aCbz-protected carbamate 10, deprotection of the Cbz group in 6, dimerization of 7 with a pentfluorophenyl-activated biscalboxylic acid 11,\(^{16}\) and deprotection of the Boc groups.

The effect of JM608 and JM642 on alternative splicing was investigated on pre-mRNA of the Ldb3 gene in the C2C12 DM1 cell model conditionally expressing r(CUG)\(_{100}\) repeat RNA.\(^{37}\) (Figure 2a) In the control cells without expression of r(CUG)\(_{100}\) the percentage of exon 11 exclusion in the Ldb3 gene was about 81 ± 1.7%, while the fraction in the DM1 cell model expressing r(CUG)\(_{100}\) was 53 ± 1.9% (Figure 2b). After the treatment of the DM1 cell model with JM642 for two days, the mis-splicing of Ldb3 pre-mRNA was significantly rescued in a dose-dependent manner, increasing exon 11 exclusion up to 77 ± 2.5% with 80 μM. The observed rescue effect of JM642 on the mis-splicing is statistically significant (**P < 0.01) at the concentrations higher than 30 μM. The effect of a monomer JM608 on the recovery in mis-splicing was 58 ± 1.9% at 80 μM. For the reference, cytotoxicity of JM608 and JM642 to the C2C12 DM1 cell model was not apparent over the treatment range (data not shown).

We then investigated the effect of JM642 on the mis-splicing of pre-mRNAs in the DM1 mouse model (HSA\(^{13}\)), which expresses r(CUG)\(_{20}\) and exhibits the mis-splicing of Clcn1 and Atp2a1 pre-mRNAs.\(^{38}\) JM642 (10 mg kg\(^{-1}\) or 20 mg kg\(^{-1}\) per day) was administrated to the HSA\(^{13}\) mice (n = 3 in each group) by daily intraperitoneal (i.p.) injection for five days. The fraction of exon 7a exclusion for the Clcn1 gene was 85 ± 0.53% for the wild type mice and 44 ± 2.4% for the HSA\(^{13}\) mice. (Figure 3a) Mis-splicing of Clcn1 has been suggested to cause myotonia.\(^{13}\) Treatment of the HSA\(^{13}\) mice with i.p. JM642 (10 and 20 mg kg\(^{-1}\)) rescued the mis-splicing in the Clcn1 gene, leading...
to an exclusion rate of 61 ± 2.3% (P = 0.03) and 70 ± 2.3% (P = 0.01), respectively, although an improvement of phenotypic myotonia was not apparent due to the partial rescue of splicing. The rescue effect of JM642 was also observed in Atp2a1 mis-splicing. In the wild-type mice, the inclusion rate for exon 22 is 100 ± 0%, whereas the inclusion fraction of exon 22 in the HSA mouse was 16 ± 2.4% (Figure 3b). After administration of 10 and 20 mg kg⁻¹ of JM642, the inclusion rate improved to 32 ± 2.5% (P < 0.05) and 74 ± 6.0% (P < 0.01), respectively. Toxicity was not observed within the mouse model over this treatment range. These results demonstrated the rescue effect of JM642 on mis-splicing of Clcn1 and Atp2a1 pre-mRNAs in DM1 in vivo.

Having observed the significant effect of JM642 and somewhat moderate effect of JM608 on the rescue in mis-splicing of genes in DM1 cell and mouse models, we have investigated the origin of these biological effects. The current hypothesis on the expected therapeutic effects of small molecules in the treatment of DM1 stems from the competitive binding of small molecules with RNA-binding proteins to the aberrantly expanded CUG repeat RNA in the nucleus. To know if JM608 and JM642 could fit this hypothesis, we looked at the binding of these molecules to the CUG repeat RNA with the SPR assay. The biotin-labeled r(CUG)₉ repeat RNA and r(CCG)₉ repeat RNA as control were immobilized through the tri-ethylene glycol linker to the avidin-coated sensor surface, and the analyte molecule was sequentially added with the increased concentration to the surface (single cycle kinetic analysis).

The SPR response curves obtained for JM608 and JM642 from the same sensor surface of r(CUG) repeat RNA were quite different in terms of the shape of the curve, which characterizes the association and dissociation kinetics as well as the affinity. The SPR profiles obtained for JM608 showed the rectangular shape indicating a rapid association and dissociation kinetics. (Figure 4a) The lowest concentration necessary for the significant SPR response under the conditions was 63 nm. The apparent dissociation constant (K_d(app)) of JM608 to the r(CUG)₉ repeat RNA was determined 1.2 μM based on the assumed 1:1 binding isotherm.

In contrast, SPR response curves obtained for JM642 were quite characteristic, showing a broad parabola shape without any plateau region. (Figure 4b) The lowest concentration of JM642 for producing a significant SPR response was 6.3 nm, which is one order of magnitude smaller than that of JM608, suggesting a positive effect of dimerization of JM608 on the binding to the CUG repeat. The parabola shape observed for the response curves is unique and is likely due to the dimeric form. The SPR response increased as the duration in applying JM642 prolonged. However, the SPR signal started to decrease while JM642 was kept applying to the surface. In general, SPR responses reach the plateau or steadily increase due to the equilibrium shift toward the ligand-bound state from the free unbound state in the bulk solution. The characteristic phenomena in SPR analysis of JM642 are likely due to conformational changes on the JM642-CUG RNA complex on the surface after initial complex formation. The significant effects of the linker length and structure connecting two isoquinoline chromophores on the binding to r(CUG) observed in the SPR analysis may support the above speculation. (Figure S1 in the Supporting Information) SPR responses on the r(CCG) repeat RNA surface were weak for both JM608 and JM642, even at 1.0 and 0.1 μM, respectively.

To gain insight into the possibility of competitive binding of JM642 with RNA-binding proteins on CUG repeat RNA, we have investigated the disruption of the ribonuclear foci in DM1 patient-derived myoblast cells by JM642 treatment. Untreated DM1 myoblasts showed the formation of ribonuclear foci (Figure 5a). The percentage of cells showing foci positive nucleus was 41 ± 7.0% among 255 cells examined. Upon treatment with 30 μM JM642, the number of cells showing the foci positive nucleus dropped to 6.7 ± 1.3% among 286 cells counted. Since the FISH probes capture the CUG repeat RNA, the CUG repeat RNA was suggested to dissociate from the aggregates forming foci in the cell nucleus upon JM642 treatment.

In summary, a newly developed small molecule JM642, a dimeric form of 5-substituted-1,3-diaminoisouquinoline derivative
JM608, rescued the mis-splicing in both DM1 cell and mouse models. The increased affinity and the different modes of the binding of JM642, as compared to JM608 in SPR assay in vitro likely attributed to the difference of biological activity in the DM1 cell model. Disruption of the ribonuclear foci in the DM1 cell model also supported the possibility of JM642-binding competitively with RNA-binding proteins. Overall, JM642 could be a useful molecular tool for the studies on the biological responses induced by expanded CUG repeat.

**Experimental Section**

**Studies on rescue effect of small molecules on the DM1 cell model**

A conditional cell model for the analysis of MBNL1 splice regulatory activity has been established, as reported previously. Briefly, C2C12 mouse muscle cells were co-transfected with pLC16 containing 800 CTG repeats and plasmid PhiC31 encoding PhiC31 integrase (Addgene, Cambridge, MA). Transfection was performed using Nucleofector technology (Lonza, Basel, Switzerland) according to the manufacturer’s program B-32. Stably transfected clones were selected with puromycin (1.25 μg/mL). Transcription across the expanded repeat was activated by Cre recombinase-mediated excision of a transcription terminator cassette. C2C12 cells with recombination were selected using hygromycin B (300 μL/mL). RNA was harvested after 2 days of incubation with JM608 and JM642. RNA extraction and analysis of the splicing pattern were carried out as described below. WST-1 assay was performed according to the manufacturer’s instructions (Roche, Basel, Switzerland).

**Studies on rescue effect of small molecules on the DM1 mouse model**

Mouse handling and experimental procedures were performed following the Osaka University guidelines for the welfare of animals and were approved by the institutional review board. Homozygous HSA40 transgenic mice of line 20b (FVB inbred background) were treated with indicated dose and period at indicated dose and period by daily i.p. injection. After treatments, mice were sacrificed, and the rectus femoris (quadriceps) muscle was obtained for splicing analysis. RNA extraction and analysis of the splicing pattern were carried out as described above.

**RNA extraction and splicing analysis**

Total RNA extraction from model cells, cDNA synthesis, and polymerase chain reaction (PCR) amplification were performed as described previously. The PCR products were separated by agarose gel electrophoresis, and the gel was stained with GelRed (Biotium, Hayward, CA). The gel was imaged using a Typhoon laser fluorimeter (GE Healthcare, Pittsburgh, PA) and the products quantified using ImageQuant (GE Healthcare).
