Abstract

Alteration in size of gingiva is one of the clinical features of periodontal disease. Increase in size of gingiva, which is termed as gingival enlargement or gingival overgrowth is a common clinical sign of gingival disease and a matter of great clinical concern. Increase in size alters the physiologic contour of gingiva, creates areas of plaque accumulation, interferes with regular oral hygiene procedures and creates aesthetic problems. In severe cases, it interferes with mastication and phonation. Enlargement may involve one or more components of gingiva. Depending on the involvement of components of gingiva and distribution, gingival enlargement can be localized, generalized, marginal, papillary, diffuse and discrete. Depending on etiology and pathogenesis, it can be classified as inflammatory enlargement, fibrotic enlargement, combined enlargement, enlargement associated with systemic conditions, neoplastic enlargement and false enlargements.

Introduction

Inflammatory gingival enlargement is most common type of overgrowth, which manifest because of increase in volume of gingival tissue in response to local microbial irritation. Inflammatory enlargement may be acute or chronic. Fibrotic gingival enlargement or non-inflammatory fibrous gingival overgrowth is believed to be the result of genetic predisposition or adverse effect of drug. Large number of drugs and genetic disorders are associated with occurrence of gingival overgrowth in susceptible individuals. They may be [1],

- Drug induced gingival enlargement
- Idiopathic gingival enlargement

Drug induced gingival enlargement

The drugs that are reported to be associated with gingival overgrowth are anti-convulsants, immune suppressants and calcium channel blockers (Table 1). Despite their pharmacological diversity all these drugs have similar mechanism of action at cellular level. They are known to inhibit intracellular calcium ion induced influx. Therefore the clinical features of gingival
over growth (Figure 1), by these agents and even the histologic appearance are reported to have common characteristics such as increase in extra cellular ground substance, number of fibroblast and acanthosis of epithelium.

Figure 1: Generalized enlargement of marginal gingiva, attached gingiva and interdental papillae.

**Anticonvulsants**

These are the drugs which are used to control epileptic seizures. Clinically it may manifest as generalized hyperplasia in mouth, but it is most severe in maxillary and mandibular anterior region. The 1st change noted is a painless bead like enlargement of gingiva, starting with one or two interdental papillae. The surface of gingival shows an increase in stippling and finally a cauliflower, warty or pebbled surface. Hyperplasia may develop massively covering a considerable portion of the crown. They may interfere with occlusion, increase plaque accumulation, resulting in secondary inflammatory process.

Laboratory studies on phenytoin induced enlargement have observed fibroblast like cell proliferation, proliferation of epithelium, increased synthesis of Glycosaminoglycans sulfate and reduced degeneration of collagen. Phenytoin induced reduction of folic acid leads degenerative changes in epithelium, increased synthesis of Glycosaminoglycans and reduced degeneration of collagen. Phenytoin was directly a enlargement, while no association was found post threshold serum phenytoin and gingival enlargement. Girgis et al found a direct relationship between gingival enlargement in 50% of patients, while no relationship and even an inverse relationship was found in rest 50%.

Some studies have found that pre threshold serum phenytoin was directly an enlargement, while no association was found post threshold phenytoin and gingival enlargement. Girgis et al found a direct relationship between gingival enlargement in 50% of patients, while no relationship and even an inverse relationship was found in rest 50%.

Studies have demonstrated that oral hygiene procedures may limit the severity of the lesion but are unable alone to lead to the reversal of the condition.

**Immunosuppressants**

Cyclosporine is a potent immunosuppressive agent used to prevent organ transplant rejection and to treat several disease of autoimmune origin. Clinically it is similar to that induced by dilantin. Mechanism of action of cyclosporine is not fully understood; however, blood and cellular immunity response seems to be influenced by selective and reversible inhibition of T helper cells. There is disagreement between severity of gingival enlargement in blood and saliva. Some studies have reported that development of gingival enlargement requires a threshold of drug concentration in blood plasma, while its severity is not associated with the dose. The dosage 500mg is considered as threshold.

**Calcium channel blockers**

Calcium channel blockers induces direct dilation of coronary arteries and arterioles, improving the oxygen supply to the heart muscles. It is used in the treatment of acute and chronic coronary insufficiency. Gingival over growth occurs in 20% of cases. The stratified squamous epithelium covering the gingival is thick and has a keratinized layer. The rete pegs are extremely long sometimes called “test pegs” with considerable confluence seen.

Calcium channel blockers affect the Ca metabolism by reducing the intra cellular Ca flow and limiting the production of active collagenase. Gingival enlargement occurs by taking 30–100mg Nefedipine per day.

**Idiopathic gingival enlargement**

It is also termed as gingivostomatitis, elephantiasis, idiopathic fibromatosis, hereditary gingival hyperplasia and congenitally familial fibromatosis. It is a proliferative fibrous lesion that causes aesthetic and functional problems. Both genetically and pharmacologically induced forms of gingival enlargement exists. Clinically it is seen on attached gingiva, gingival margina and interdental papilla. It appears as pink, firm and leathery with pebbled surface. Teeth are completely covered. In severe cases jaw appears distorted due bulbous enlargement.

**Pregnancy induced gingival enlargement**

The prevalence of pregnancy gingivitis changes from 35–100%. The gingiva shows increased level of inflammation often characterized by edema, colour and contour change and propensity to bleed on gentle stimulation (Figure 2). The marginal gingival tends to be more prominent than facial and lingual surfaces. And inflammatory reaction to the local irritants that occurs after 3rd month of pregnancy is called pregnancy tumour. This lesion appears as discrete, mushroom, flattened spherical masses, that protrude from gingival margin, more frequently interproximal space and are attached by sessile or pedunculated base.

**Puberty induced gingival enlargement**

It is immunological type of gingival enlargement which occurs in both male and females in pubertal age groups. It involves mainly marginal and interdental gingiva (Figure 3). It is characterised by prominent bulbous interproximal papilla. After puberty the enlargement undergoes spontaneous reduction but does not disappear until local irritants are removed.

Management

Treatment for drug induced hyperplasia includes substitution with another drug. Sodium valproate has been used as alternative to dilantin sodium in management of epilepsy. Anti-hypertensives other than calcium channel blockers may be considered for replacement of Nifedipine. Tacrolimus has been used successfully as calcium channel blocker. Most of the gingival enlargement during pregnancy can be prevented by removal of local irritants and institution of fastidious oral hygiene. Hyperplasia at puberty can be managed by removal of lesions along with elimination of irritating factors [8].

Conclusion

Gingival enlargement has varied presentations, hence diagnosis of these entities become challenging for the clinician. Detailed investigation is necessary. So prompt diagnosis and removal of the etiologic factors is the main treatment objectives.
