Abstract

Geologic processes at convergent plate margins control geochemical cycling, seismicity, and deep biosphere activity in subduction zones and suprasubduction zone lithosphere. International Ocean Discovery Program Expedition 366 was designed to address the nature of these processes in the shallow to intermediate depth of the Mariana subduction channel. Although no technology is available to permit direct sampling of the subduction channel of an intraoceanic convergent margin at depths up to 19 km, the Mariana forearc region (between the trench and the active volcanic arc) provides a means to access materials from this zone.

Active conduits, resulting from fractures in the forearc, are prompted by along- and across-strike extension that allows slab-derived fluids and materials to ascend to the seaﬂoor along associated faults, resulting in the formation of serpentinite mud volcanoes. Serpentinite mud volcanoes of the Mariana forearc are the largest mud volcanoes on Earth. Their positions adjacent to or atop fault scarps on the forearc are likely related to the regional extension and vertical tectonic deformation in the forearc. Serpentinite mudﬂows at these volcanoes include serpentinized forearc mantle clasts, crustal and subducted Pacific plate materials, a matrix of serpentinite muds, and deep-sourced formation fluid. Mud volcanism on the Mariana forearc occurs within 100 km of the trench, representing a range of depths and temperatures to the downgoing plate and the subduction channel. These processes have likely been active for tens of millions of years at the Mariana forearc and for billions of years on Earth.

At least 19 active serpentinite mud volcanoes have been located in the Mariana forearc. Two of these mud volcanoes are Conical and South Chamorro Seamounts, which are the farthest from the Mariana Trench at 86 and 78 km, respectively. Both seamounts were cored during Ocean Drilling Program Legs 125 and 195, respectively. Data from these two seamounts represent deeper, warmer examples of the continuum of slab-derived materials as the Pacific plate subducts, providing a snapshot of how slab subduction affects fluid release, the composition of ascending fluids, mantle hydration, and the metamorphic paragenesis of subducted oceanic lithosphere. Data from the study of these two mud volcanoes constrain the pressure, temperature, and composition of fluids and materials within the subduction channel at depths of up to 19 km. Understanding such processes is necessary for elucidating factors that control seismicity in convergent margins, tectonic and magma genesis processes in the volcanic arc and backarc areas, fluid and material fluxes, and the nature and variability of environmental conditions that impact subseaﬂoor microbial communities.

Expedition 366 focused on data collection from cores recovered from three serpentinite mud volcanoes that define a continuum of subduction-channel processes to compare with results from drilling at the two previously cored serpentinite mud volcanoes and with previously collected gravity, piston, and remotely operated vehicle push cores across the trench–proximal forearc. Three serpentinite mud volcanoes (Yinazao, Fantangisha, and Asút Tesoro) were chosen at distances 55 to 72 km from the Mariana Trench. Cores were recovered from active sites of eruption on their summit regions and on the flanks where ancient flows are over lain by more recent ones.

2 Expedition 366 Scientists’ addresses.
Recovered materials show the effects of dynamic processes that are active at these sites, bringing a range of materials to the seafloor, including materials from the crust of the Pacific plate, most notably subducted seamounts (even corals). Most of the recovered material consists of serpentine mud containing lithic clasts, which are derived from the underlying forearc crust and mantle and the subducting Pacific plate. A thin cover of pelagic sediment was recovered at many Expedition 366 sites, and at Site U1498 we cored through distal serpentine mudflows and into the underlying pelagic sediment and volcanic ash deposits. Recovered serpentinitized ultramafic rocks and mudflow matrix materials are largely uniform in major element composition, spanning a limited range in SiO₂, MgO, and Fe₂O₃ compositions. However, variation in trace element composition reflects interstitial water composition, which differs as a function of the temperature and pressure of the underlying subduction channel. Dissolved gases H₂, CH₄, and C₂H₆ are highest at the site farthest from the trench, which also has the most active fluid discharge of the Expedition 366 serpentinite mud volcanoes. These dissolved gases and their active discharge from depth likely support active microbial communities, which were the focus of in-depth subsampling and preservation for shore-based analytical and culturing procedures. The effects of fluid discharge were also registered in the porosity and gamma ray attenuation density data indicated by higher than expected values at some of the summit sites. These higher values are consistent with overpressured fluids that slow compaction of serpentine mud deposits. In contrast, flank sites have significantly greater decreases in porosity with depth, suggesting that processes in addition to compaction are required to achieve the observed data. Thermal measurements reveal higher heat flow values on the flanks (~31 mW/m²) than on the summits (~17 mW/m²) of the seamounts. The new 2G Enterprises superconducting rock magnetometer (liquid helium free) revealed relatively high values of both magnetization and bulk magnetic susceptibility of discrete samples related to ultramafic rocks, particularly dunite. Magnetite, a product of serpentinitization, and authigenic carbonates were observed in the mudflow matrix materials.

In addition to coring operations, Expedition 366 focused on the deployment and remediation of borehole casings for future observatories and set the framework for in situ experimentation. Borehole work commenced at South Chamorro Seamount, where the original-style CORK was partially removed. Work then continued at each of the three summit sites following coring operations. Cased boreholes with at least three joints of screened casing were deployed, and a plug of cement was placed at the bottom of each hole. Water samples were collected from two of the three boreholes, revealing significant inputs of formation fluids. This suggests that each of the boreholes tapped a hydrologic zone, making these boreholes suitable for experimentation with the future deployment of a CORK-Lite.

**Background**

Geologic processes at convergent plate margins affect geophysical cycling and fluxes, seismicity and natural hazards, crustal and mantle evolution and mixing, and biosphere activity and population dynamics in subduction zones. To constrain these processes, inputs and outputs must be quantified. Quantifying inputs into a convergent plate margin is accomplished by sampling the downgoing plate prior to subduction to provide a geochemical, physical, and mechanical reference. The study of the output in terms of magma and volatiles in volcanic arcs and in backarc basin settings constrains processes that occur deep within the subduction zone, but such studies of subduction systems are incomplete, lacking an understanding of processes that occur between the time the subducting plate enters the trench and the time it reaches the zone of magma genesis beneath the arc. The Mariana convergent system provides natural windows into this zone.

The Mariana convergent system is a nonaccretionary-type convergent plate margin (Uyeda and Kanamori, 1979). Here, fluids and materials rise from the subducted Pacific plate within long-lived permeable pathways through the overlying Philippine plate. Such pathways are maintained with across- and along-strike extension (Fryer and Salisbury, 2006). Vertical tectonic deformation is another potential process that shapes fault patterns in the forearc. Vertical deformation occurs when Cretaceous Pacific plate guyots are subducted. In contrast, the zone between the trench and the region of arc magmatogenesis is not accessible in accretionary forearcs. Here, deep-sourced fluids ascend through imbricate fault systems and splay in a thick prism of the accreted sediments. Transit of deep-sourced fluids through the prism results in reactions with a compositionally heterogeneous package of sediments, obfuscating the composition of the deep-sourced fluid. Thus, the Mariana forearc region is unique in the world today in that it provides direct access to deep-sourced fluids and material from the subduction channel and suprasubduction zone via active serpentinite mud volcanism. Furthermore, ascending deep-sourced fluids with elevated pH, methane, and hydrogen concentrations relative to seawater support subsurface microbial communities. Such fluids vent at summit seeps, often supporting megafaunal communities (Fryer, 2012; Ohara et al., 2010).

Therefore, to study processes in the Mariana forearc we chose four active serpentinite mud volcanoes (Yinazao, Fantangisña, Asùt Tesoro, and South Chamorro) for investigation during Expedition 366 (Figure F1; Table T1). Operations included coring at summit and flank sites on Yinazao, Fantangisña, and Asùt Tesoro Seamounts; deploying a screened casing for future borehole experiments on the summits of each; and revitalizing the borehole observatory (CORK) at South Chamorro Seamount (Ocean Drilling Program [ODP] Site 1200).

Yinazao Seamount (informally called Blue Moon Seamount) lies on the eastern edge of a forearc graben about 55 km from the Mariana Trench axis (Figure F1; Table T1). Of the three mud volcanoes cored during the expedition, Yinazao Seamount is the closest to the trench, and the subducting slab lies approximately 13 km below its summit (Oakley et al., 2007, 2008). Like the many other serpentinite mud volcanoes that populate the southern half of the Mariana forearc, Yinazao Seamount is situated along a zone of weakness in the overriding plate's lithosphere. The fault trend that controlled the growth of the edifice has a northeast–southwest trend and intersects a northwest–southeast trend immediately south.

A primary feature of the summit of Yinazao Seamount is a fault scarp with a maximum throw of about 80 m that is collinear with the northeast–southwest fault trend. The eastern half of the summit is shallower, and the overall morphology of the summit suggests a right-lateral motion on a fault with dip-slip to the northwest. The offset on the fault is apparently a combination of footwall uplift (eastern block) and downdrop of the hanging wall to the northwest (western block). This deformation may have directed the egress of rising fluids to the southwest edge of the summit area where a spring was located. Systematic variation in interstitial water composition from serpentinite mud piston cores collected from the research vessel (R/V) Thomas G. Thompson in 2003 confirmed the
Table T1. Critical parameters of the deep-sourced fluid from five Mariana serpentinite mud volcanoes. Depth-to-slab was determined by seismic reflection profiles for Yinazao, Fantangisña, and Asùt Tesoro Seamounts (Oakley et al., 2007, 2008; Oakley, 2008), and by equilibrium mineral assemblages in metamafic clasts for South Chamorro and Conical Seamounts (Maekawa et al., 1993; Fryer et al., 2006; Garib, 2006). Distance to trench and temperature of slab from Hulme et al. (2010). Depth-to-slab measurements for Yinazao, Fantangisna, and Asùt Tesoro from Oakley et al. (2008) and Oakley (2008). Depth-to-slab measurements for South Chamorro and Conical are extrapolation estimates (see text).Interstitial water measurements from Expedition 366, Mottl et al. (2003, 1992), Mott (2004), and Hulme et al. (2010). Download table in CSV format.

| Measurement          | Yinazao | Fantangisña | Asùt Tesoro | South Chamorro | Conical |
|----------------------|---------|-------------|-------------|----------------|---------|
| Distance to trench (km) | 55      | 62          | 72          | 78             | 86      |
| Depth-to-slab (km)    | 13      | 14          | 18          | 18             | 19      |
| Temperature of slab (°C) | ~80    | ~150        | ~250        | ~250–350       | ~250–350|
| Interstitial water pH | 11.2    | 11.0        | 12.5        | 12.5           | 12.5    |
| Interstitial water Ca (mM) | 64     | 90          | 0.1         | 0.3            | 1       |
| Interstitial water K (mM) | ~1     | 5           | 14          | 19             | 15      |

The summit region of Asùt Tesoro Seamount has a prominent mound at the intersection of the two fault trends. The summit mound is roughly circular and about 3 m in diameter and 200 m high. At its apex, it has three smaller circular mounds. One is centered at the middle of the ~1.5 km plateau on top of the mound and is about 350 m in diameter and 40 m high. The two other mounds are about 200 m in diameter and 20 m high. The two smaller mounds lie side by side west of the larger mound and are both overlapped by it. An ROV transect of the larger mound was conducted in 2003 with the Jason II (J2-034 and J2-036) from west to east. The highest rate of fluid discharge occurred in the middle of the surveyed mound on the summit of the seamount.

South Chamorro Seamount is located about 78 km from the trench, with the subducting slab approximately 18 km below its
summit; it was drilled during ODP Leg 195 (Figure F1; Table T1). This seamount is primarily composed of unconsolidated flows of serpentinite mud with clasts consisting dominantly of serpentinitized peridotite but also includes greenschist and blueschist rock fragments from the subducted Pacific plate (Shipboard Scientific Party, 2002). The summit shows active fluid seepage of slab-derived fluids with megafaunal assemblages that include mussels, gastropods, worm tubes, and galatheid crabs (Fryer and Mottl, 1997). Subsurface microbes include archaea (Mottl et al., 2003; Curtis et al., 2013) and Bacteria (Takai et al., 2005). Even with evidence for fluid flow from a deep source (Hulme et al., 2010), temperatures measured in the uppermost 1 m at Site 1200 are between 2°C and 3°C, which is just above the bottom water temperature of 1.7°C.

During Leg 195, a borehole observatory (CORK) was deployed. This original-style CORK included a 202.8 m long casing with a screened section from about 148.8 to 202.3 meters below seafloor (mbsf). This screened section provides a conduit for formation fluids at depth to exchange with fluids within the borehole. When the borehole is open at the seafloor, fluids naturally discharge (Wheat et al., 2008). However, the lack of latches to maintain formation pressure and the small diameter imposed by the original-style CORK limit the usefulness of this installation. The plan for Expedition 366 was to remove the CORK body, leaving the hole open for a future ROV deployment of a CORK-Lite (Wheat et al., 2012).

**Objectives**

The four primary scientific goals outlined in the Expedition 366 Scientific Prospectus were to assess (1) mass transport processes in the Mariana forearc region, (2) spatial variability of slab-related fluids, (3) metamorphic and tectonic history and physical properties of the subduction zone, and (4) biological activity associated with deep-derived subduction zone material. To meet or address these goals, the specific objectives were to gain better insight into mass transport (fluids and solid materials) in the Mariana forearc region and its relationship to subduction zone tectonics and subseafloor biological processes. The sites chosen for drilling on the three target serpentinite mud volcanoes span different distances (and depth to slab) from the Mariana Trench. Results from Expedition 366 will therefore complement previous drilling completed during ODP Legs 125 and 195. In addition, the long-term goal of the expedition was to establish borehole observatory sites at the summits of the three seamounts targeted for coring.

To meet the specific objectives for coring during Expedition 366, the operational plan was to (1) intersect mudflows of variable composition that mantled the flank of each edifice and, at the two that were known to be active, recover conduit muds from areas near active springs; (2) potentially date discrete mudflows paleontologically, should there be sediment layers between them; (3) determine variability in the composition of rock clasts in the mudflows; (4) investigate potential systematic variability in degree of serpentinitization (possibly lower degrees at initiation of mud volcanism via conduit “throat clearing” or greater on the flanks where rock clasts may have reacted more fully with enclosing serpentinite muds and fluids); (5) examine transport conditions of muds and interstitial waters; (6) provide a measure for the scale of potential fluid discharge characteristics (e.g., diffuse versus channelized); (7) determine the composition of fluid from depth; and (8) collect samples for the study of microbial/viral community interactions at depth and if possible near the underlying forearc sediment surface under a range of conditions.

The primary objective for establishing borehole observatories was to deploy three screened and cased boreholes that bisect hydrologic zones (aquifers), one at each of the three summit sites on Yinazao, Fantangisña, and Asùt Tesoro Seamounts. These boreholes, each sealed with cement at their base, would then serve as the foundation for a return mission with an ROV to replace CORK-Lites within the cased holes. CORK-Lites would enable downhole monitoring, experimental capabilities, and collection of pristine deep-source fluids within a gas-tight sampling system for dissolved gas analyses. Given the original-style CORK at South Chamorro Seamount, the objective was to remove the CORK body so the borehole could be used for a range of experiment types and instrument sizes.

**Coring results**

Three serpentinite mud volcanoes were cored during Expedition 366 (Yinazao, Fantangisña, and Asùt Tesoro Seamounts). Cored materials were recovered from each of the summit and flank sites using a variety of coring technologies designed for maximum recovery, penetrating hard materials, or achieving a desired depth (Table T2). Thus, combined with data from Legs 125 and 195, the new data from Expedition 366 provide a continuum from relatively cool (−80°C) and shallow (−13 km) conditions at depth within the subduction channel closer to the trench to hot (−350°C) and deep (−19 km) conditions further from the trench. It is important to note that the depths to the slab given in Table T1 for Yinazao, Fantangisña, and Asùt Tesoro Seamounts are based on estimates from at least two MCS profiles across these edifices (Oakley et al., 2007, 2008; Oakley, 2008). However, for Conical and South Chamorro Seamounts there are no MCS data. As a consequence, a depth to slab estimate was determined for these edifices based on a number of assumptions. The estimate assumes (1) that the subducting Pacific plate is a smooth surface (i.e., has carried no subducted seamounts down, although the drilling results show it has), (2) that the trench itself is unperturbed by interaction with subducting seamounts and thus subtends a smooth curve that is an average of the thalweg position (Hulme et al., 2010) (bathymetry maps; e.g., Figure F1) (however, there are significant perturbations associated with impact from Pacific seamounts entering the trench), (3) that the plate subducts along the shortest perpendicular to a tangent of that average curve and that the distance of the seamount summit from the trench can be determined by measuring along that perpendicular, (4) that the angle of convergence between the Pacific plate and the trench lies along that perpendicular (though it does not), and (5) that paragenesis models using equilibrium assemblages of metamorphic minerals in subduction-channel-derived rocks recovered from coring and drilling on these two edifices do not fit a graphic model for depth to slab beneath the seamounts. The paragenesis models are described fully in Maekawa et al. (1993), Fryer et al. (2006), and Gharib (2006). Therefore, we used the depths of the three seamounts cored during this expedition, as estimated by MCS data, to fit a line defining a depth versus distance from the curve representing an average of the trench position and extrapolated that line to the distances of the summits of Conical and South Chamorro Seamounts as measured along the perpendicular to the tangent of the average trench–curve to establish an estimate for the depths to slab beneath those seamounts. Therefore, we caution the reader to bear in mind that depths to slab beneath the seamounts drilled during Legs 125 and 195 are certainly deeper than those drilled.
during Expedition 366 but may be subject to errors on the order of perhaps a few kilometers.

Materials recovered during drilling operations were analyzed using standard techniques commonly utilized duringIODP expeditions. We present a summary of these data types and an initial interpretation organized by shipboard laboratory, providing an integrated model of subsurface processes based on data from each of the three cored sites. Each laboratory began the process of comparing and contrasting results from summit sites, which represent the most pristine materials in terms of transport from depth, and flank sites, where eruptive materials overlie previous deposits and have undergone alteration reactions made possible through diffusion exchange with overlying oxic bottom seawater. Ultimately, results from the various laboratories will be integrated to provide greater constraints for evaluating mass transport, temporal variability, metamorphic and tectonic history, and microbial mechanisms and activity.

Lithostratigraphy, petrology, and structure

Material recovered during Expedition 366 consists primarily of serpentinite mud (Zone 1 in Figure F2) containing lithic clasts derived from the underlying forearc crust (Zone 2 in Figure F2) and mantle and the subducting Pacific plate. A thin cover of pelagic sediment was found at many sites, whereas pelagic sediments and volcanic ash deposits were cored underlying serpentinite mudflows on the distal flanks of one of the three cored seamounts (Zone 3 in Figure F2). The conceptual model for serpentinite mud volcanism processes within forearc/subduction complex is best described with a cross-section perpendicular to the trench (depicted schematically in Figure F2). Here, we describe in more detail the results from each site cored during Expedition 366.

The bulk of the material recovered in the cores is serpentinite mudflow matrix (Zone 1 in Figure F2). The matrix ranges from pale green to dark blue-gray, except in the upper few meters of material recovered on the flanks of the seamount, where the serpentinite is typically oxidized to a yellow-orange color. The serpentinite mud consists largely of clay- to silt-sized serpentine grains plus accessory phases such as Fe oxide (magnetite and/or hematite), brucite, spinel, calcite, hydrogarnet, talc, tremolite, and chlorite. Secondary alteration minerals include bogdochrome group minerals, clays, aragonite, and gypsum. Authigenic aragonite, as single acicular needles or radiating clusters of acicular crystals, is common in the upper few tens of meters. Some serpentinite mud horizons appear to be reworked; these horizons may contain pelagic nanofossils, volcanic ash, and mineral fragments (e.g., clinopyroxene). Clay contents vary from <1 vol% to more than 35 vol% lithic clasts, with a mode of around 5 vol% lithic clasts.

Ultramafic clasts are the dominant clast type (Zone 4) and are mainly serpentinitized harzburgite (<<5% clinopyroxene) with less common dunite and pyroxenite. The range in degree of serpentinization is broad, 30%–100% of the original material. Serpentinitization is commonly pseudomorphic, and primary modes are inferred in most of the peridotites because the grain sizes for pyroxene (bastite) and spinel are largely unaffected. Primary textures were identified in most samples based on relict mineral phases or pyroxene-spinel relations. All dunites and most harzburgites (from Sites U1491, U1493–U1495, and U1497) are inferred to be porphyroclastic or coarse tabular primary textures with elongate, deformed olivine and spinel. Enstatite, smaller strain-free neoblasts of olivine, as well as holly leaf–shaped interstitial spinel (e.g., Mercier and Nicolas, 1975; Lenoir et al., 2000). Olivine in some dunite samples occurs as scattered fragments with the same optical orientation that together form...
Figure F2. Idealized cross-section of the Mariana forearc setting, including the relative positioning of serpentinite mud volcanoes. Tectonic Zones 1–6 in the forearc subduction zone complex are keyed to core images in this figure and to some of the photomicrographs in Figure F3. Figure modified after Fryer et al. (1999).

much larger (up to 1 mm) deformed primary grains. These textures imply that serpentinitic materials have undergone solid-state deformation in the lithosphere at relatively low temperatures.

By contrast, harzburgites from Sites U1492 and U1498 are characterized by protogranular textures, with vermicular spinel-pyroxene clusters inferred to represent decompression breakdown of garnet (Smith, 1977; Bhanot et al., 2016). The protogranular textures are overprinted by a subsequent texture formed in response to diffuse porous flow and reactive melt transport. Orthopyroxene has ragged lobate margins with sharp cusps that point into olivine grain boundaries (or former grain boundaries); some olivine grains have flat facets against orthopyroxene, signifying crystal growth faces in the presence of melt; and olivine also occurs as euhedral to anhedral postcumulus textures in cumulate rocks. These textures are inferred to be melt infiltration textures formed by reactive diffuse porous flow of a low-silica melt. This melt is undersaturated in orthopyroxene, which melted incongruently to form a silica-rich melt and new olivine. Because the delicate apices of interstitial pyroxene would likely be destroyed by solid-state flow in the lithosphere, we propose that this texture formed in the asthenosphere during melt production in response to subduction initiation.

No systematic changes of the serpentine textures were observed between the different sites (Zones 1–4 in Figures F2, F3). Serpentinitized ultramafic rocks display mainly pseudomorphic mesh and bastite textures that replaced olivine and orthopyroxene, re-
pectively. Such textures are likely composed of lizardite and chrysotile, but this assumption needs to be verified with postexpedition analyses. The mesh displays pronounced blue color at Yinaizao and Fantangisña Seamounts. Such coloration could be attributed to serpentinite composition. Rare interpenetrating textures, which could correspond to the high pressure and temperature serpentinite variety (antigorite), were mainly observed at Fantangisña and Asüt Tesoru Seamounts. Serpentinitized ultramafic clasts are commonly crosscut by massive to fibrous veins of serpentine (chrysotile), crystallizing into isolated networks of fractures, some of which are conjugate and some of which display crack-seal-like textures within the vein cen-
ter. Although the cored serpentinite mud volcanoes are located at different distances from the Marian Trench, the absence of a clear variation of serpentinite textures in the ultramafic clasts suggests that the serpentinitization process occurs continuously from the slab/mantle interface to the surface and that each mud volcano in-
cludes ultramafic clasts that were serpentinitized at a range of depths (temperature and pressure). Late stages of serpentinite alteration were observed within each mud volcano, mainly corresponding to breccia consisting of fragments of serpentinite minerals, ser-
pentinites, and clay minerals cemented by carbonate. The fragmen-
tation obliterated previous serpentinite and mantle textures.

Crustal rocks derived from the underlying forearc crust and the subducting Pacific plate (Zones 3 and 6, respectively) were observed at several sites, but they form a major fraction of the recovered clasts at three sites: U1496 (Asüt Tesoru summit), U1497 (Fan-
tangisña summit), and U1498 (Fantangisña flank). Low-grade meta-
morphosed sedimentary rocks and basalts were recovered from the sum-
mit site of Asüt Tesoru Seamount (Site U1496). The sedimen-
tary clasts are fossiliferous cherty limestones. Some mafic volcanic clasts are dolerites and augite-phyric vitrophyres, and some contain salinity and greenish gray serpentinite pebbly mud. The brownish gray
pelagic sediment was recovered in the first cores from most flank
sites; thus, paleontological analysis will help constrain the date of
the most recent activity at each site.

Site U1491

Site U1491 is located on the flank of Yinaizao Seamount near the
base of a slight bathymetric valley. Mixed pelagic muds containing a
variety of clastic materials were typically found at the tops of Holes
U1491A (1.3 mbsf), U1491B (19.4 mbsf), and U1491C (34.2 mbsf) (Table
T2). Beneath these pelagic sediments in Holes U1491B and U1491C, we
recovered sequences of normally graded carbonate-
dominated breccia–conglomerate that are likely the result of com-
mination and drilling disturbance (via heave from the drill string)
and serpentinite muds containing clasts of serpentinitized ultramafic
and occasionally carbonate (foossiliferous reef limestone). The na-
ture of the lithologic units recovered in Holes U1491A–U1491C is
consistent with the interpretation that these units represent ser-
pentinite mudflows, the deepest of which tapped a source of car-
bonate clasts and serpentinitized ultramafic rocks that are likely far
less matrix supported than observed previously. The source of the
carbonate materials is possibly an underlying subducting Cretaceous
seamount.

Site U1492

Site U1492 is located on the summit of Yinaizao Seamount along
the extension of an inferred normal fault. Holes U1492A, U1492B,
U1492C, and U1492D were drilled to 38.3, 51.4, 139.1, and 228.8
mbsf, respectively; no materials were recovered from Hole U1492D
(Table T2). Recovered materials from Holes U1492A and U1492D
consist of an uppermost unit of blue-gray to light brown (oxidized)
serpentinite pebbly mud with lithic clasts, Hole U1492B has a thin
(<0.4 m thick) upper unit of pelagic sediment overlying a lower unit
of blue-gray serpentinite pebbly mud. The mudflow matrix contains
5%–10% lithic clasts of serpentinitized ultramafic rock. The occur-
rence of pelagic mud in Hole U1492B at the summit rim of Yinaizao
Seamount is consistent with the observed sequence of predomi-
nantly serpentinite muds containing heavily serpentinitized ultra-
mafics clasts capped by a veneer of more oxidized, seawater-altered
serpentinite muds and a spotty, thin pelagic sediment cover. Hole
U1492C has an intermediate unit of green serpentinite mud. Ultra-
mafics clasts in the lowermost portions of the boreholes display the
most extreme degrees of serpentinitization, with continuous transi-
tion toward plastically deforming components. Conversely, ultra-
mafics clasts in the brown to light green uppermost intervals retain
their hardness and frequently exhibit milder degrees of alteration.

Sites U1493, U1494, and U1495

Sites U1493, U1494, and U1495 were drilled on a line from
south to north on the south flank of Asüt Tesoru Seamount (Table
T2). The deepest site (U1493; 3359 meters below sea level [mbsl]) is
the closest to the distal southern edge of the edifice. Hole U1493A
was drilled to 0.1 mbsf, and Hole U1493B was drilled to 32.6 mbsf.
Site U1494, with only one hole (39 mbsf) at 2200 mbsf, is close to
the midflank of the edifice, and Site U1495, at 1400 mbsf, is located
just south of the summit mound.

Serpentinite muds are covered by brownish pelagic mud at Sites
U1493 and U1495 that contains volcanic ash, foraminifers, nanno-
foils, and minor diatoms and radiolarians. The thickness of the
pelagic muds varies between sites, with approximately 80 cm in
Hole U1493B, 0 cm in Hole U1494A (likely lost during mudline at-
tempts), 25 cm in Hole U1495A, and 40 cm in Hole U1495B. Hole
U1494A recovered an interval of mass flow between 6.9 and 8.78
mbsf that contains reworked serpentinite mud, volcanic ash, and
boninite and volcanic glass (possibly boninitic), and occasionally
carbonate clasts and serpentinized ultramafic rocks that are likely far
more matrix supported than observed previously. The source of the
carbonate materials is possibly an underlying subducted Cretaceous
seamount.
serpentinite pebbly mud contains authigenic aragonite crystals and lithic clasts. The greenish gray serpentinite pebbly mud contains lithic clasts and occasional layers of matrix-supported breccia–conglomerate.

The three sites share a generally common stratigraphy that differs in detail with location. Uppermost recoveries consist of layers of either reddish oxidized sediments or mixed blue-gray and orange (oxidized) serpentinite pebbly mud. The pelagic sediments include microfossils and volcanic ash. The thickness of pelagic sediments generally decreases upslope. Beneath the most oxidized layer of serpentinite mud, mudflows tend to grade from pale green to dark blue with depth although they are intercalated with lighter green serpentinite muds in some depth intervals.

Small clasts of mafic igneous rocks were enclosed in the mudflows. They include metabasalts displaying green (chlorite and possibly epidote) and pale red (carbonate) layers. The compositions of the mafic rock clasts indicate that they are part of the subducted oceanic crust from the Pacific plate, altered by low-grade metamorphism and seafloor hydration processes.

Site U1496

Material from the summit of Asùt Tesoru Seamount (Holes U1496A [44.8 mbsf] and U1496B [36 mbsf]); Hole U1496C had no recovery) is characterized by a dominance of pale green serpentinite mud with a low proportion of lithic clasts compared with the seamount’s flanks and other sites (Table T2). The pale green serpentinite mud is typically soupy or very soft due to high gas contents and often continued to out-gas days later. Dark blue serpentinite mud is uncommon, but when present it is characterized by higher clast counts. These characteristics are consistent with an active summit site that is currently producing high-pH water and abiotic hydrogen and methane.

Although less common than at other sites, hard rock clasts derived from the seamount summit mound provide important insights into the plumbing system of the mud volcano. Most common are ultramafic clasts, typically highly serpentinitized harzburgites with less common dunite and orthopyroxenite. These materials likely derive from the underlying forearc mantle lithosphere.

We also recovered clasts of mafic metavolcanic and sedimentary rock. Sedimentary clasts include a fossiliferous, cherty limestone that may be pre-Eocene in age. Mafic metavolcanic clasts include dolerites with pink titanaitugite and augite-phryic vitrophyres. The presence of titanaitugite in these rocks indicate that their protoliths were alkali basalts. They are interpreted to be recycled material from subducted seamounts of the Pacific plate.

Site U1497

Four holes were drilled at Site U1497 on the summit of Fantangisña Seamount (Holes U1497A [34.2 mbsf] and U1497B [23.8 mbsf]; no recovery from Holes U1497C and U1497D) (Table T2). The occurrence of deformed sediments and volcanicic rocks at this site suggests that a significant fraction of the material entrained by this mud volcano is derived from the subducting Pacific plate. In particular, titanaitugite-bearing volcanicic rocks imply mildly alkaline volcanic series in an ocean island seamount. In addition, deformed sediments appeared to contain microfossils, such as radiolarians, that are representative of older (Mesozoic?) sediment from the Pacific plate. The presence of ultracataclasite, which requires severe brittle deformation, is unlikely to have occurred in sediments that were lying on top of the upper plate. Deformation of the Pacific plate as it bends on approach to the Mariana Trench and moves within the subduction channel could easily entail sufficient strain to produce these textures.

Mantle-derived harzburgites from Site U1497 are fully serpentinitized but retain evidence of primary textures. They are characterized by pseudomorphs of orthopyroxene porphyroclasts that are highly elongated (in one case 4 mm × 0.4 mm), with kink folds and undulatory extinction. Spinel occurs in association with pyroxene and with subhedral to holly leaf shapes, 1–2 mm in size. We interpret these observations to indicate altered porphyroclastic textures, consistent with deformation at relatively low temperatures and moderate to high rates of strain. The (meta-)sediments are characterized by recrystallization of calcareous and siliceous microfossils. The degree of recrystallization indicates low-grade metamorphic conditions. Both the metasedimentary and metavolcanic rocks are brecciated to varying degrees. Brecciation resulted in the development of fine-grained cataclasite to ultracataclasite domains. The very fine grained sediments (shales and sandstones) were partly transformed into ultracataclasite shear zones with rounded clasts. The very small grain size (<2 µm) within these shear zones indicates that the general deformation mechanism was ductile flow. Shear might have been localized along these shear zones. In general, brecciation (fracture) implies cataclastic deformation mechanisms (fracture and friction) at low-grade, moderate to high strain rates.

Site U1498

Site U1498 is located on the flank of Fantangisña Seamount. Hole U1498A (181.6 mbsf) is on the extreme southwestern flank, very close to the distal edge of the edifice and immediately downslope from a distinct break in slope of the lower flank (at 3507.5 mbsl) (Table T2). Hole U1498B (260 mbsf; 3296.0 mbsl) is ~700 m upslope northeast of Hole U1498A. Lithologies recovered at Site U1498A, with increasing depth in hole, include yellowish oxidized pelagic muds with pelagic microfossils; intercalated blue, green, and yellow-orange serpentinite mudflow matrix silts and sands; partially serpentinitized ultramafic rocks (harzburgite and dunite); mafic metavolcanic rocks and boninites; and, at the bottom of the hole, nanofossil- and volcanic ash-rich sedimentary rocks (siltstones and fine sandstones). In addition, Hole U1498B returned a large (~2 m) compound clast of ultramafic rock, mafic metavolcanic rock, metalimestone, and metachert, likely originally within a serpentinite mud matrix, which was not recovered because the use of rotary coring likely washed out any existing matrix. All but the ultramafic rock is suspected to be part of a Cretaceous seamount.

The recovered clasts from Hole U1498B provide a particularly illuminating sequence of materials that deserves more detailed description. With increasing depth, the recovery includes (1) partially altered (to clay) serpentinitized ultramafic rock clasts (stones and boulders), (2) serpentinitized pebbly mud with pebbles of serpentinitized ultramafics, (3) boulders of serpentinitized ultramafics with numerous fractures filled with chrysotile, and (4) boulders of metabasite and cherty limestone and clasts of boninite and volcanic glass. These clasts and boulders were likely embedded within serpentinite pebbly mud (observed adhering to some of them), much of which was probably washed out during rotary coring. The mudflow matrix is well preserved in Sections 366-U1498B-7R-1 through 21R-1, 0–30 cm, with intermittent boulders, although it does show drilling disturbance (flow-in). The most surprising recovery occurs in Core 21R. In Section 21R-1, 116 cm, there is a preserved and presumed inverted primary contact between a boulder of metabasite (35–116 cm; interpreted to be “igneous basement”) and a boulder of cherty limestone (116–132 cm and continuing into Section 22R-1,
0–81 cm; interpreted to be “sedimentary cover,” i.e., originally overlying the metabasite). The deformed cherty limestone appears to contain microfossils such as radiolarians that are common in older sediments from the Pacific plate. The texture and mineralogical composition of the metabasite (greenstone with chlorite and amphibole) and cherty limestone indicate low- to possibly medium-grade metamorphic overprint of these lithologies. These two boulders are clearly distinct from the volcanic rocks (boninites and forearc basalts) of the overriding Mariana forearc crust. The metabasite and limestones are consistent with a lower plate origin, and their paragenesis and position within the serpentinite mudflow matrix material suggests a dynamic overturning during exhumation. Furthermore, preserved cataclastic faults and extensional structures within these boulders (high-angle normal faults and extensional veins) may be related to (1) shearing within the subduction channel and bending of the lower plate during subduction, (2) accretion and vertical tectonism of intact seamount/guyot masses into the forearc region, or (3) faulting during the early stages of exhumation. The presence of ultracataclasite in the cherty limestone boulder requires severe brittle deformation that would not likely occur in sediment from the overriding forearc crust. At the base of Section 22R-CC, 81–93 cm, is a serpentine mudflow matrix that continues to Section 23R-1, 12 cm. A boulder of greenstone with numerous fractures infilled with white secondary precipitate was observed in Section 23R-1, 12–81 cm. At Section 24R-1, 9 cm, we recovered a contact between serpentine mud matrix containing serpentinized ultramafic rock and dark-gray, pelagic, vitric silt and volcanic ash that contains microfossils. We thus achieved our goal of penetrating within the sediment that predates serpentinite flows at this site. Beginning at Section 27R-1, 13 cm, we recovered intercalated pelagic, light tan to medium brown layers of pelagic, silty clay and volcanic ash that persisted to the end of the hole.

**Sediment and rock chemistry**

A selection of representative serpentinite mudflow matrix, various igneous and sedimentary rocks, serpentinite mud, and sediments recovered during Expedition 366 were analyzed with the new portable X-ray fluorescence spectrometer (pXRF). On the basis of these and visual results, a subset of materials was powdered for a suite of ship- and shore-based analyses (Table T3). In addition, a thin section was located next to each of the powered rock samples. At sea, powered samples were analyzed using standard inductively coupled plasma–atomic emission spectroscopy (ICP-AES) techniques to measure concentrations of Al₂O₃, CaO, Fe₂O₃, MgO, MnO, Na₂O, SiO₂, TiO₂, Ni, Cr, Sr, Ba, Sc, V, and Zr and the pXRF was used to determine concentrations of Al₂O₃, Fe₂O₃, CaO, Cr, Cu, MgO, Mn, Ni, Cr, Zn, SiO₂, and Sr (Table T4).

Recovered serpentinites are largely uniform in composition, with serpentinized ultramafic rocks and serpentinite muds spanning a limited range in SiO₂, MgO, and Fe₂O₃ compositions (Figure F4). No significant site-to-site or seamount-to-seamount variability was evident in these major elements or in the variations in Al₂O₃, which range from 0.1 to 1.7 wt% with a mean value of ≈0.6 wt% (Table T3). This range is similar to the ranges reported by Savov et al. (2005a, 2005b, 2007) for serpentinized ultramafic clasts from Conical Seamount and for mudflow matrix and clasts from South Chamorro Seamount.

Fluid-immobile minor and trace elements Ni, Cr, Zn, V, and Sc show no clear distinctions from site to site or seamount to seamount in the serpentinitized ultramafic rocks (Figure F5). V, Sc, Mn, and Zn show regular patterns of variation; these elements appear not to be redistributed by fluid-rock exchanges associated with serpentinization. TiO₂ variations in serpentinites differ from those of the other immobile elements in that there may be site-related variability, with higher values evident for Site U1496 samples. However, Ti concentrations are close to the limits of detection using the shipboard ICP-AES, with only a fraction of our samples yielding detectable readings. It is equally possible that this small number of higher values were analytical artifacts.

Major and trace elements that are sensitive to redistribution by fluid-rock exchange processes with ultramafic rocks show more variable patterns (Table T3). CaO concentrations show considerable variability, ranging from <0.01 to >10 wt% across a limited range in MgO values (Figure F6). A few samples analyzed from all three seamounts include rocks with both CaO ≥ 10 wt% and high MgO, suggestive of ultramafic cumulate bulk compositions for some of the serpentinized ultramafic rocks. A plot of Na₂O versus MgO (Figure F6) shows an evident distinction between the serpentinized ultramafic clasts, which have Na₂O values of <0.4 wt%, and the serpentine muds, which range as high as 2.0 wt% Na₂O. Seamount-to-seamount variations are evident; serpentine muds from the Asùt Tesoru summit site (U1496) have higher Na₂O concentrations than those from the summits of Yinazao Seamount (Site U1492) or Fantangisña Seamount (Site U1497). Intrastitial waters at the Asùt Tesoru summit extend to markedly higher abundances of Na than do those from the summits of Fantangisña or Yinazao Seamounts. Thus, the high Na₂O in Asùt Tesoru muds may reflect equilibration with these Na-enriched intrastitial waters.

Sr concentrations in serpentinites are highly variable, ranging from <5 to >6000 ppm (Table T4). As with Na₂O, the serpentinized ultramafic clasts are lower in Sr abundance (≤100 ppm), relative to the serpentine muds (100–6000+ ppm; mean = 600 ppm). In addition, there are clear seamount-to-seamount differences in the serpentine composition of the muds, likely related to equilibrium with their associated intrastitial waters. Yinazao Seamount muds (Site U1492; intrastitial waters > 700 μM) are markedly higher in Sr than those from Asùt Tesoru Seamount (Site U1496; intrastitial waters ≤ 10 μM). The highest Sr and Ca in serpentinite mud samples were found in near-surface cores and relate to the presence of authigenic aragonite and/or gypsum.

A small number of metamorphosed mafic volcanic and crustal rocks (sedimentary breccias, metamorphosed basalts, and boninites) were recovered, primarily from the summits of Asùt Tesoru Seamount (Site U1496) and Fantangisña Seamount (Sites U1497 and U1498) (Tables T3, T4). The metabasalts show elevated concentrations of TiO₂ (1.6%–3.3%) and K₂O (2.7%–6.7%) and range from 16 to 18.6 wt% in Al₂O₃ with highly variable MgO (2.5%–11.3%) and Na₂O (0.8%–3.5%) (Figure F7). Analyzed metabasite samples have Ni concentrations of ~55 ppm, high V and Sc concentrations (up to 280 and 28 ppm, respectively) (Figure F5). Sr concentrations between 54 and 236 ppm (Figure F6), Ba concentrations up to 88 ppm, and Zr concentrations between ~240 and 470 ppm. There is evidence for within-clast heterogeneity; samples from each of the two core sections characterized by mafic clasts (Sections 366-

---

U1496B-8X-CC and 10F-2) show considerable variability in a number of immobile and mobile elements. Plotted on the Shervais (1982) V-Ti tectonic provenance diagram, these rocks are similar to those from the intraplate/alkali basalt field (Figure F5).

The metamorphosed mafic rocks resemble a subset of (1) samples recovered from dredges along a wall of a forearc graben north of the sites drilled during Expedition 366 (Johnson and Fryer, 1990) and (2) trachybasalts recovered from the western Pacific immediately outboard of the Mariana Trench (http://www.iedadata.org). These mafic rocks do not resemble the forearc tholeiite and boninite lavas that were known to comprise the volcanic crust of the outer Mariana forearc (e.g., Reagan et al., 2010). Thus, the most likely origin for these rocks is the downgoing Pacific plate, where seamounts that expose alkalic lavas are currently subducting.

**Interstitial water geochemistry**

Studies of interstitial water geochemistry from summit sites cored during Expedition 366 focused on collecting end-member compositional information, thus improving our overall understanding of the deep-sourced processes. In contrast, studies of interstitial waters from the flanks of the three cored seamounts focused on elucidating compositional changes of interstitial waters with time in the context of water-rock reactions, diffusive exchange with seawater, microbial activity, and processes associated with pelagic sediments that underlie serpentinite mud volcanoes in the Mariana forearc.

Analyses of dissolved gases $H_2$, $CH_4$, and $C_2H_6$ provide important insights into the physical and chemical conditions of the deep source. High concentrations of dissolved $H_2$, $CH_4$, and $C_2H_6$ were
measured in samples from the summit of Asùt Tesoru Seamount, and comparatively low but significant levels were detected at Yinazao Seamount summit and flank sites. Variability in gas compositions among the three seamounts indicate differences in serpentinization and fluid migration processes. Dissolved H₂ and CH₄ (Figure F8A) show two groupings broadly consistent with thermodynamic estimates of serpentinization-driven H₂ production (McCollom and Bach, 2009) and subsequent abiotic (Fischer-Tropsch Type) synthesis processes at depth.

The chemical composition of deep-sourced interstitial waters was assessed along the continuum from shallow to deep source and from closest to farthest from the trench (Yinazao, Fantangisña, Asùt Tesoru, South Chamorro, and Conical Seamounts) (Table T1; Figure F9). Fluids from the summits of Yinazao and, to a lesser extent, Fantangisña Seamounts show elevated Ca and Sr and low to extremely low K, Na, Cl, SO₄, B, and Na/Cl concentrations relative to bottom seawater. In contrast, fluids that upwelled at the summit of Asùt Tesoru seamount are similar in composition to those from South Chamorro and Conical Seamounts, with extremely high pH values (up to 12.4), Ca and Sr depletions, and marked enrichments in carbonate alkalinity, dissolved inorganic carbon (DIC), dissolved...
organic carbon (DOC), NH₄, Na, K, Na/Cl, and B. Na concentrations are higher at Asùt Tesoru than any of these five seamounts (Figure F9; see discussion below).

We mapped changes in the chemical composition of interstitial waters across the Mariana forearc in relation to subduction-related prograde diagenetic and metamorphic reactions that may trigger fluid and elemental releases (Figures F10, F11). Processes that occurred early (shallow) within the subduction system (i.e., Yinazao and Fantangisña Seamounts) were likely dominated by diagenesis and opal dehydration, whereas later processes (deeper) (i.e., Asùt Tesoru Seamount) included decarbonation and clay mineral decomposition (Fryer, Pearce, Stokking, et al., 1990; Haggerty, 1991; Haggerty and Chaudhuri, 1992; Haggerty and Fisher, 1992; Mottl, 1992; Mottl and Alt, 1992; Fryer et al., 1999; Mottl et al., 2003, 2004; Hulme et al., 2010; Wheat et al., 2008, 2010). Higher DIC at greater depths-to-slab is likely linked to carbonate decomposition within the slab. DIC reacting with H₂ from serpentinization could produce CH₄, light alkanes, or short-chained organic molecules (e.g., acetate and formate). Ca and Sr were sequestered from the fluids by carbonate precipitation (the lack of calcite in core samples from Asùt Tesoru Seamount suggests this reaction occurred slightly closer to the trench, which would exhaust Ca with continued CO₃²⁻ production). Although Asùt Tesoru Seamount’s interstitial waters are broadly similar to those studied at South Chamorro and Conical Seamounts, they are nonetheless distinct, with much higher Na and Cl concentrations and 3–4 times lower B contents. These differences likely reflect the lowest pressure-temperature (P-T) prograde metamorphic mineralogical reactions, impacting slab sediments and saponites that result in fluid release (Figure F11).

This slab signal is overprinted by low-temperature peridotite-seawater reactions and microbial interaction with fluids, particularly near the seafloor (Mottl et al., 2003; Takai et al., 2005; Curtis et al., 2013) and on the flanks of the seamounts. Initial interstitial water results from five flake sites cored during Expedition 366 indicate that the fluids are mixtures of slab-derived fluids that have undergone various degrees of alteration with serpentine materials in the mud flows and exchange with overlying seawater.

Microbiology

Sample recovery

Microbiology sampling during Expedition 366 focused on exploring the limits of microbial life and viral components in serpentinite mudflow habitats across multiple depths using cultivation-based and cultivation-independent molecular biological approaches and microscopy. Sampling efforts targeted both near-surface and deeper whole-round cores, especially if there was evidence of a transition across gradients of microbiologically affecting compounds and gases (e.g., hydrogen, methane, hydrogen sulfide, and sulfate). Two 20 cm long whole-round samples were collected at each sampled depth for general microbial analyses (Table T5). Additional whole-round samples were collected for individual investigations. Samples were collected within the context of tracer studies to assess potential contamination resulting from the drilling and sample recovery processes.

Microbiological samples will be analyzed on shore using an array of microbial community–level interrogation techniques. Samples were fixed for total cell counts to quantify microbial biomass. Other samples were maintained at 4°C for multiple cultivation techniques (including fluorescence-activated cell sorter [FACS] high-throughput media screening and detection of adaptation to physical parameters such as pressure tolerance). Other samples were flash-frozen at ~80°C for molecular analyses, including small-subunit (SSU) ribosomal gene amplicon sequencing (to address community structure in greater detail), functional gene detection and quantifi-
cation through real-time quantitative polymerase chain reaction (qPCR), and single-cell genomics (to specifically address individual cell contributions). In addition, metagenomics of the entire microbial community and metatranscriptomics of the most highly expressed genes will be used to establish metabolic potential and deeper ecological and evolutionary relationships. Lastly, samples were preserved for enumerating viral counts and assessing viral diversity.

**Contamination testing**

Perfluoromethylcyclohexane (PMCH) was used at the first two sites (U1491 and U1492) and the last site (U1498), and perfluoromethyldecane (PFMD) was used at the remaining sites (U1493–U1497). This split was partially due to tracer availability and partially to our ability to establish proper protocols for both perfluorocarbon tracers (PFTs). Data obtained from PMCH measurements show relatively clean (uncontaminated) drilling by advanced piston corer (APC) and half-length APC (HLAPC) operations at Site U1492. This analysis, however, indicates disturbance in cores and drill fluid intrusion at Site U1498, which was drilled using a rotary core barrel (RCB) technique. Generally, drill fluid intrusion into samples was higher at sites where drilling became difficult and required the use of either extended core barrel (XCB) or RCB drilling.

Analysis of the PFMD data does not provide a distinct quantitative assessment of contamination, unlike the PMCH tracer. PFMD is a relatively new method for contamination tracing, and the results from this expedition strongly reinforce the need for further method development if it is to be used when coring sediment.

**Shipboard DNA extraction and qPCR**

Shipboard DNA extraction from serpentinite mud samples was unsuccessful using a standard qPCR protocol (e.g., Lever et al., 2015). Additional analysis shows high adsorption of DNA to serpentinite minerals; thus, improvements in DNA extraction protocols in terms of adsorption prevention will be necessary for further DNA extractions. Performing qPCRs on board the R/V JOIDES Resolution is feasible and can expand the range of available shipboard analyses for future expeditions.

**Physical properties**

Among the eight sites that were drilled during Expedition 366, the physical properties obtained at the two summit sites at Yinazao and Asút Tesoru Seamounts (Sites U1492 and U1496, respectively) are distinct. Physical property values are usually associated with consolidation and compaction of sedimentary deposits (e.g., bulk density, porosity, thermal conductivity, and shear strength); however, data from the two summit sites, at the active spring areas observed from the ROV Jason II, indicate that serpentinite muds at these sites were underconsolidated.

For example, the porosity data collected during Expedition 366 followed two trends (Figure F12). One trend was defined by data from summit Sites U1492 and U1496 and ODP Site 780 (Conical Seamount). At each of these sites, porosity decreases with depth from seafloor values of 60%–70% to values of 45%–55% at 120 mbsf. An exponential trend was fit to the Site U1492 data, resulting in an Athy’s coefficient (Athy, 1930) of 0.36, indicating that this summit site is slightly underconsolidated (Bekins and Dreiss, 1992). Both sites (U1492 and U1496) are located in areas of fluid discharge where discharge rates exceed 10 cm/y (Hulme et al., 2010). These sites targeted our best estimate for the location of the current conduit for fluid and material flow from depth. A slight compaction effect is suggested in Holes U1492A and U1492B by the overall increasing trend in gamma ray attenuation (GRA) density with depth, whereas Hole U1492C, the closest one to the presumptive conduit, has lower GRA values and a rather constant trend to the bottom of the hole (~130 mbsf) (Figure F13). Likewise, consolidation and compaction trends with depth in Hole U1496A at Asút Tesoru Seamount show a slight increase of bulk density, but no such trend was observed in Hole U1496B. The rather constant GRA bulk density and porosity values observed in Holes U1492C and U1496B, both located less than 20 m from the presumptive conduit area, appear to be influenced by overpressured fluids localized in the immediate region of the central conduit system, which minimized the compaction of serpentinite mud deposits at these holes. In contrast, GRA density increases in Holes U1492A, U1492B, and U1496A suggest this overpressure effect associated with the conduit system is not effective 50 to 100 m from the area with the most active fluid discharge. A width of less than ~100 m for the active conduit at Yinazao and Asút Tesoru Seamounts is consistent with conduit diameters described for other mud volcanoes, which are considerably smaller than the size of the mud volcanoes themselves (Krastel et al., 2003).

There is a greater decrease in porosity, however, with depth at the other sites (mostly flank sites) to porosity values less than 30% at only 40 mbsf. The Athy coefficient fit at Site U1494, for example, is 17.3—unreasonably high for a compaction trend. Below 40 mbsf,
Porosity values stabilize and remain fairly constant with depth. Such low porosities (and high Athy coefficients) are suggestive of processes other than compaction being responsible for the observed data.

Although similar, there are slight peculiarities in data from the other sites. Even the two sites located on the edge of seamount summits, Sites U1495 and U1497, show behavior more typical of flank sites. The porosity trend at Site U1495 resembles that at flank sites on other seamounts but is more extreme, decreasing from 57% to 36% at only 4 mbsf.

The third summit site (Site U1497 on Fantangisña Seamount) is distinct from the other two summit sites. The porosity trend with depth is comparable to those described for the other flank sites (Figure F12). These trends suggest that either the mud volcano has not been active recently or subsurface flow in this area was either diffuse, compartmentalized, and not necessarily vertical or was following trends in local faults associated with the slump features at the summit.

**Downhole measurements**

Temperature measurements using the advanced piston corer temperature tool (APCT-3) were attempted 14 times, resulting in 11 records that were used to estimate formation temperatures. These estimates were combined with measured seafloor temperatures and thermal conductivities from collected cores to calculate heat flow for the three summit sites and two of the flank sites (Table T6). The summit heat flow values range from 16.8 to 17.8 mW/m², whereas the two flank sites range from 30.5 to 40.0 mW/m² (Figure F14).

These values and differences are consistent with data from the summit of South Chamorro Seamount, which average 15 mW/m² in ODP Holes 1200A and 1200E (Shipboard Scientific Party, 2002), and those collected on the flanks of Conical Seamount at DSDP Sites 458 and 459 (Uyeda and Horai, 1982).

Wireline logging was conducted in Hole U1498B after penetrating to 260 mbsf. The triple combo tool string was used to measure magnetic susceptibility, natural gamma radiation (NGR), electrical resistivity, borehole diameter, and temperature of borehole fluids. The downhole logging data show excellent agreement with the shipboard data. The NGR data are consistent with 9 m of pelagic sediment at the sediment/water interface that was not recovered during coring operations and registered the cherty limestone and metabasalt units. Two possible layers of pelagic sediments, one each at 118 and 137 mbsf intercalated within the serpentinite (e.g., pale streaks in intervals 366-U1498B-13R-4, 21–25 cm, and 15R-3, 6–10 cm). Here, peaks in NGR values are at similar levels to those of Unit
Assuming ash-rich pelagic sediments that are thought to exist in the upper 9 m of Hole U1498A. Additional evidence for layers of pelagic sediment is the lack of evidence in the resistivity data for clasts. The resistivity data were useful for detecting large clasts.

**Paleomagnetism**

The new 2G Enterprises superconducting rock magnetometer (SRM; liquid helium free) was installed at the start of Expedition 366. Paleomagnetic analyses of archive halves and representative discrete samples were performed. The natural remanent magnetization (NRM) of almost all section halves was measured at 5 cm intervals after 0, 5, 10, 15, and 20 mT alternating field (AF) demagnetization steps. The use of principal component analyses provided consistent NRM inclination and declination values between section halves and discrete samples.

A pervasive vertical magnetic overprint was imparted to the cores, likely by the drilling process. In some cases, overprinting was largely demagnetized by AF demagnetization in peak fields of 5 mT; in many intervals, however, enough of the overprint remains after the 20 mT demagnetization step that inclination values remain anomalously high. The axial dipole inclination was expected to be between 29.5° and 33.2° at the latitude (15.8°–18.1°N) of coring operations. We searched for paleomagnetic reversals for magnetostratigraphic dating in the volcanic ash-rich pelagic sediments that overlie the serpentinite muds, but no clear reversals were found. In some cores, a particularly high intensity overprint was observed between 3 and 5 m above the base of the core, for example, Cores 366-U1492C-5F and 8F (Figure F15).

Magnetic susceptibility levels are generally high, reflecting the high concentrations of magnetic minerals, particularly magnetite, in the cores. Magnetite was of interest because it was produced during serpentinization reactions, to a greater or lesser extent depending on the iron content of the initial minerals. Magnetic susceptibility is higher at the Asùt Tesoru sites, averaging over 1000 × 10⁻⁵ SI compared to the other two mud volcanoes (Figure F15). Magnetic susceptibility levels are generally high, reflecting the high concentrations of magnetic minerals, particularly magnetite, in the cores. Magnetite was of interest because it was produced during serpentinization reactions, to a greater or lesser extent depending on the iron content of the initial minerals. Magnetic susceptibility is higher at the Asùt Tesoru sites, averaging over 1000 × 10⁻⁵ SI compared to the other two mud volcanoes (Figure F15). There is some local correlation between magnetic susceptibility levels and the color of the serpentinite mud, but no correlation across all of the sites. In Hole U1496A, for example, the darker mud between 26 and 27 mbsf has five times lower susceptibility than the surrounding pale green serpentinite mud, whereas in Hole U1493B,
the pale green serpentinite mud at 20–23 mbsf has much lower susceptibility than the blue-gray mud above and below it.

Magnetic intensities are high, given the high concentrations of magnetic minerals, but there is an unexpectedly large range of intensity values (Figure F15). At Site U1496, the paleomagnetic intensity is relatively low and correlates with magnetic susceptibility, as expected from a consistent lithology and magnetization process. At other sites, however, magnetic intensity is relatively high compared to magnetic susceptibility, and the correlation between the two is less clear, perhaps due to the difficulty in demagnetizing the variable overprint in many of these cores. NRM intensity generally ranges from 1.0 × 10⁻³ to 1.0 A/m, reaching maximum values of 10 A/m in Hole U1494A in dark bluish gray serpentinite pebbly mud. Generally, ultramafic rock clasts present relatively high values of both magnetization and bulk magnetic susceptibility in discrete samples.

Cased borehole operations and results

Each of the four serpentinite mud volcanoes visited during Expedition 366 (Yinazao, Fantangisña, Asüt Tesoro, and South Chamorro Seamounts) included a borehole operational component. The goal was to deploy an infrastructure that intersected an active hydrologic flow of deep-sourced fluid along a continuum of conditions across the forearc. These boreholes include screened sections to allow formation fluids to enter and are designed for future deployments of CORK-Lites (Wheat et al., 2012). This construct will enable the community to use the boreholes for scientific endeavors, including but not limited to monitoring physical and chemical changes, in situ passive experimentation, and manipulative experiments to address a range of potential scientific questions that center on geophysical, geochemical, and/or microbial studies. A CORK-Lite has a modular design that includes multiple ports for experiments and sensors inside or outside of the CORK body and for large-diameter (25 cm) experiments and sensors to be deployed within the boreholes, which can be either sealed or allowed to discharge.

South Chamorro Seamount (Site 1200)

Given the limitations of the original-style CORK that was deployed at Site 1200 during Leg 195, the plan was to remove the CORK body, thus leaving the hole open for a future ROV deployment of a CORK-Lite (Wheat et al., 2012). While attempting to remove the CORK body, the latch rods failed to remove the portion of the CORK that latches into the casing hanger, forming a seal and focusing discharge up a steel pipe that contains the seal sleeve. This steel pipe parted above the seal sleeve. However, the CORK is likely sealed with access to the underlying casing via a portion of a PVC insert that was deployed in 2009, providing a conduit for future sampling activities. The recovered CORK body included white and reddish material on the outside that was collected for microbial and mineralogical analyses. About seven limpets also were recovered from the CORK body and preserved for shore-based identification.

Yinazao (Site U1492), Fantangisña (Site U1497), and Asüt Tesoro (Site U1496) Seamounts

A casing string was deployed after an initial hole was drilled into the summit region at Yinazao, Fantangisña, and Asüt Tesoro Seamounts. The casing string included at least three joints of screened casing, placing the screened casing as deep as possible and well below the near-surface microbial "transition" layer (e.g., Mottl et al., 2003). Difficulties experienced during the deployment of the first casing string changed the depth and design of the second and third deployments.

The initial borehole casing string was deployed at Site U1492. This casing string was 211 m long with a screened section at 153–199 mbsf. The other two casing strings were shorter (~110 m long) with screened sections at ~35–70 mbsf. A cement plug was deployed at the base of each of the three casing strings because of a failure during the deployment of a mechanical bridge plug at Site U1492; however, later operations did break the bridge plug free so the base of the casing string could be cemented. These cementing operations were important because serpentinite material flowed into the base of the casing string at Site U1496 within hours of landing the casing within the casing hanger, filling the bottom 7 m of the open cased hole. We returned to two of the three boreholes (Sites U1496 and U1497) to check the status of the cement and collect a water sample with the water-sampling temperature probe (WSTP) within these two boreholes. We did not have time to return to the cased borehole at Site U1492 after cementing operations.

The cement plug was reached at both sites (U1496 and U1497) several days after cementing operations. The cement was in place as planned and likely sealed the boreholes from intruding material. Water samples were collected from the middle of the upper screened casing joint at both sites. Analysis of this water indicates a mixture of seawater and formation fluid. The Site U1496 sample includes the highest dissolved gas measurements made during the expedition, highlighting the importance of sampling formation fluids directly, thus without the artifacts induced by the coring and sample handling process.

Each of the three new boreholes tapped an active hydrologic zone with formation fluids that discharge into the casing and vent at the seafloor. By deploying a CORK-Lite with an ROV, the community will be able to collect pristine fluids (especially dissolved gases) that are unaffected by sampling artifacts. The community will also be able to collect and/or filter tens to thousands of liters of formation fluid for chemical, microbial, and viral analyses, volumes that are not possible to obtain during standard IODP coring operations. The deployment of CORK-Lites also opens the cased boreholes to a range of sensors, samplers, and experiments that will allow scientists to build a network of borehole observatories, monitoring, and manipulations at the seafloor or within the borehole and with the boreholes sealed or open to discharge.

Preliminary scientific assessment

Expedition 366 successfully cored the flanks and summit regions of three Mariana forearc serpentinite mud volcanoes, each located at varying depth to the subducting Pacific plate, to characterize processes associated with the formation and activity of these mud volcanoes. The expedition was designed to examine subduction-related processes in terms of the relationship between geochemical cycling, seismicity, and deep biosphere activity in subduction zones and in the lithosphere of the subducting plate. The intent of the expedition was to address how these processes vary spatially along the strike of the Mariana system and with depth to the subduction channel (~13 to 19 km below). The results from this expedition complement those from previous Legs 125 and 195 at two other serpentinite mud volcanoes, Conical and South Chamorro Seamounts, both farther from the trench than the three edifices cored during Expedition 366.
Previous drilling during Leg 125 used rotary coring, and poor recovery failed to provide much of the mudflow matrix in which the rock clasts were entrained. Leg 195 used APC/XCB coring and recovered many thin mudflows, some with more than 100% recovery, because the matrix contained gases that expanded upon recovery. During Expedition 366, all three coring systems were used, each for a specific purpose. Drilling results during Legs 125 and 195 proved that the mudflows contain, in part, materials from the subduction channel below the edifices. Expedition 366 recovered a greater diversity of subduction channel material from closer to the Mariana Trench, thus from shallower depth-to-slab than material recovered in the two previous legs. Rock clasts and matrix muds from the serpentinite flows recovered during Expedition 366 provide a far better view of the regional processes that have affected the forearc. Furthermore, the cased holes with screened sections that were drilled into the summit regions of these three mud volcanoes now constitute the first regional laboratory for monitoring subduction-related phenomena in the trench-proximal region of a nonaccretionary, intraoceanic, convergent plate margin.

We achieved or will achieve with shore-based analyses all four of the overarching scientific goals outlined in the Expedition 366 Scientific Prospectus. These goals were to assess (1) mass transport processes in the Mariana forearc region, (2) spatial variability of slab-related fluids, (3) metamorphic and tectonic history and physical properties of the subduction zone, and (4) biological activity associated with deep-derived subduction zone material. Associated with these four scientific goals are nine specific objectives, described below.

1. Core mudflows on the flanks of each mud volcano and recover conduit muds from areas near active springs on the summit of each mud volcano.

This objective allowed us to address both construction history and transport processes. We recovered serpentinite mudflows with variable characteristics on the flank of each edifice from Sites U1491 (Yinazao Seamount), U1493, U1494, U1495 (Asūt Tesoro Seamount), and U1498 (Fantangisña Seamount). The serpentinite mudflow matrix varies in color with depth, and although it was distinctly disturbed by flow-in during APC and XCB coring, it does preserve discrete horizons of clast content and matrix constituents. The cause of the color change in the serpentinite muds is not obvious and will become the focus of several proposed shore-based studies. Although we were without X-ray diffraction or X-ray fluorescence instruments during Expedition 366, samples analyzed with a pXRF and ICP-AES showed essentially no difference in the major elements between the compositions of the serpentinized rock clasts and muds from seamount to seamount, except for specific major and trace elements that are sensitive to redistribution by fluid-rock exchange processes. The latter elements showed more variable patterns in the matrix and fluid data, indicating a regional consistency with depth-to-slab. Expedition 366 results confirm the broad interpretation of gravity core, piston core, and submersible/ROV push core work over the past decade that revealed a regional gradient in terms of change in the composition of slab-related fluids with depth to the subduction channel, as recorded by the fluids discharging from active springs in serpentinite mud volcanoes. The enhancement of this finding as a result of Expedition 366 was that the source of most of the fluids is initially prehnite-pumpellyite facies dehydration followed by greenschist alteration and lastly blueschist dehydration and mobilization of fluid mobile elements. For example, boron and potassium data show drastic increases in the concentration in muds and fluids with distance from the trench.

There remain questions regarding the eruptive processes. Such questions would be better addressed through monitoring. For example, how variable are the volumes of erupted materials, how does the rate of fluid discharge and the stress field change during active episodes of eruption, and what controls the eruptive cycle? The planned CORK-Lite installations at the cased boreholes will be instrumental in addressing temporal-related questions.

2. Date discrete mudflows paleontologically, should there be sediment layers between them.

Dating discrete layers will better our understanding of the episodicity of the eruptions and how differences among episodes may affect transport processes. Dating will be possible because we recovered pelagic sediment overlain by flank serpentinite mudflows and were able to penetrate the underlying forearc sediments at two of the holes on Fantangisña Seamount’s flank. We recovered interlayered mudflows of clay-sized serpentinite mud of a wide variety of oxidized and unoxidized material, as well as interlayered pelagic sediments on the distal edges of Fantangisña Seamount. Very few rock clasts were found in these mudflows. Also, beneath the serpentinite on Fantangisña Seamount, we recovered ash-rich sediment with abundant microfossils. Biostratigraphic ages for the recovered sediments will be determined on shore. The recovery of this material is reminiscent of that in the deepest sediment interval (near Eocene igneous basement) in Hole 459 (Leg 60), which is located south of Asūt Tesoro Seamount (Desprairies, 1982).

3. Determine variability in the composition of rock clasts in the mudflows.

The anticipated discovery of subduction channel physical and compositional properties was realized through the recovery of numerous rock clasts. Peridotite rock clasts were present in the cores from each of the three seamounts that were drilled. They include dunites, harzburgites, and pyroxenites and vary in degree of serpentinization from 30% to 100%. The less serpentinized peridotites preserve relict olivine and orthopyroxene that will make it possible to use crystal preferred orientation analysis to study the history of stress distribution, both across- and along-strike of the entire southern Mariana suprasubduction-zone mantle wedge. Cores from the flanks of the mud volcanoes included microfossils in some mudflow intervals and beneath the distal flank of Fantangisña Seamount. Paleontologic age ranges from these will be determined to constrain temporal aspects of the history of mantle stress patterns.

We also discovered striking variability in the lithology of other rock clasts within the mudflows, and the results of shipboard observations and analysis show that all five of the serpentinite seamounts cored to date (including Leg 125 and 195 cores) contain lithologies from the subducted slab. The fact that all of these mud volcanoes tapped slab-derived fluids and erupted rock clasts from the subduction channel confirms that these edifices are indeed natural windows to slab processes. The range of recovered material from Expedition 366 is particularly illuminating because we recovered fossiliferous reef limestones and metavolcanics with alkalic provenance, as well as compositions consistent with ocean island basalts. These lithologies indicate a source from subducted Pacific plate and seamounts on it.

Also collected were clasts that span the entire range of lithospheric compositions known to have formed in the supra-subduction-zone region of the Mariana forearc crust. Thus, Expedition 366 results also confirm that serpentinite mud volcanoes erupt the entire suite of rock materials that represent the sub-surface architecture of the Mariana arc. The fact that the mud
volcanoes occur exclusively in association with forearc scarps suggests that vertical tectonism of the forearc is the rule rather than the exception.

4. **Study potential systematic variability in the degree of serpentinization of rock clasts and distinguish the characteristics of the mudflow matrix on the flanks from those in the summit conduit regions.**

Coring on the flanks of the edifices revealed for the first time that there is systematic increase in the degree of serpentinization of rock clasts and of secondary mineralization of the mudflow matrix with increasing depth down the flanks of the mud volcanoes. Most ultramafic clasts recovered from the flanks reacted to a greater extent with muds that are generally 100% serpentinized. Furthermore, individual serpentinized rock clasts are soft enough to indent with a fingernail. Reaction of the clasts with the matrix muds is evident where halos surround clasts and darken the adjacent mud. The degree of serpentinization in ultramafic clasts is variable in the summit regions, where episodicity of activity in the conduits of these edifices may cause pulsing, presumably on various timescales, of the mud matrix and fluids and may refresh the throat with new and less reacted materials.

5. **Examine transport conditions of muds and interstitial waters on the seamount flanks.**

Transport conditions of muds and interstitial waters are remarkably variable on the flanks and in the summit regions of the seamounts. Changes in the density and porosity of mudflows on the flanks of the seamounts indicate that compaction is not the only force that affects trends in these physical properties with depth. Additionally, deformation by gravitational sliding (Oakley et al., 2007) may affect these profiles, as can continued serpentinization and alteration to other phases that significantly reduce porosity. Causes for these changes in physical properties will be assessed in shore-based mineralogical analysis and rheologic studies of whole-round samples. The latter were collected and preserved for mechanical, stress, and permeability testing, including the determination of physical properties.

6. **Provide a measure for comparing the nature of hydrologic characteristics (e.g., diffuse versus channelized fluid flow) on the flanks and summit regions of the mud volcanoes.**

Systematic variations in interstitial water composition profiles from flank sites indicate no significant vertical discharge of fluids. At each of the summit sites, interstitial water compositions show clear evidence of seepage at discharge rates in excess of the serpentinite matrix, which also is ascending and constructing the dome-like features on the summit of two of the three seamounts that were cored. These results are consistent with published data that define the range and area of discharge at the summit sites.

7. **Determine the composition of fluid from depth and assess the type, extent, and effect of diageneric reactions that occurred on the flanks of serpentinite mud volcanoes.**

Systematic variations in interstitial water composition profiles from Yinazao (13 km depth-to-slab), Fantangisña (14 km), and Asüt Tesoru (18 km) Seamounts augment previous results from South Chamorro (18 km) and Conical (19 km) Seamounts (Table T1). This combination of data extends the dramatic change, noted in previous studies (Mottl et al., 2004; Hulme et al., 2010), in the compositions of the slab-derived serpentinizing fluids as the subduction channel deepens. Dramatic differences include elevated Ca and Sr and low to extremely low K, Na, Cl, SO4, B, and Na/Cl in fluids from Yinazao Seamount and, to a lesser extent, Fantangisña Seamount. In contrast, discharging fluids from Asüt Tesoru Seamount have a composition similar to that from South Chamorro and Conical Seamounts, with extremely high pH (up to 12.48), Ca and Sr depletions, and marked enrichments in carbonate alkalinity, DIC, DOC, NH4, Na, K, Na/Cl, and B. Na concentrations are higher at Asüt Tesoru Seamount than at any the five seamounts mentioned above. Chemical compositions of interstitial water from the flank sites are consistent with a mixture of slab-derived fluid and seawater. Superimposed on this mixture are diageneric changes that are evident in some of the measured chemical species.

Coupled to the seventh objective was the desire to document the composition of dissolved gases, specifically H2, CH4, and C2H6. Compositions of these gases differed from site to site, providing a measure of deep-sourced fluid composition. High concentrations of H2, CH4, and C2H6 were observed at the summit of Asüt Tesoru Seamount, and comparatively low but significant levels were detected at both summit and flank sites at Yinazao Seamount. Concentrations of H2 and CH4 show two distinct groupings: serpentinization-driven H2 production and methane production. The relationship between methane and ethane data from Asüt Tesoru, South Chamorro, and Conical Seamounts converge on a single composition that may represent the hydrocarbon values produced by abiotic (Fisher Tropsch Type) synthesis in the deep-sourced fluid.

8. **Collect samples for the study of microbial/viral community interactions in materials bathed in deep-sourced fluids, distal serpentinite mud flows, and the underlying forearc pelagic sediment.**

Whole-round samples collected for microbiological studies were subsampled for shore-based analyses to explore the limits of microbial life in serpentinite mud using cultivation-based and cultivation-independent molecular biological approaches, microscopy, and assays for the detection of viruses. Postexpedition analyses will include an array of microbial community–level interrogation techniques: (1) total cell counts to quantify microbial biomass; (2) cultivation (including FACS high-throughput media screening and detection of adaptation to physical parameters such as pressure tolerance); (3) molecular analyses, including SSU ribosomal gene amplicon sequencing (to address community structure in greater detail), functional gene detection, and quantification through qPCR and single-cell genomics (to specifically address individual cell contributions); (4) metagenomics of the entire microbial community and metatranscriptomics of the most highly expressed genes to establish metabolic potential and deeper ecological and evolutionary relationships; and (5) viral counts and diversity. The only microbial analysis conducted at sea was to assess the quality of the whole rounds via tracer analysis. Tracers were pumped into the drill string prior to and during core recovery. Systematic sampling of the cored material and overlying surficial fluids indicates that most of the whole-round samples for microbiology are suitable for continued shore-based analyses.

9. **Complete initial fabrication of borehole structures for future in situ experiments and observations.**

Three casing strings, each with three or more joints of screened casing, were deployed, one in each of the summits of the cored serpentinite mud volcanoes. These casing strings form the foundation for a future deployment of CORK-Lites (Wheat et al., 2012), which allow for a range of experiments and observations to be conducted...
simultaneously within a single structure that is open to deep-sourced fluids. We collected a water sample and measured temperature within two of the three newly deployed cased boreholes days after the bottom was sealed with cement. The recovered fluids were a mixture of seawater (drilling fluids) and deep-sourced fluid, and temperatures were higher than expected based on measurements collected during serpentinite mud coring operations. Combined, these data indicate that both boreholes tapped a hydrologic zone and active fluid discharge exists. The third site also should have active discharge based on systematic variations in interstitial water composition profiles that indicate fluid discharge rates of centimeters to tens of centimeters per year in the summit area. Similar results were observed at South Chamorro Seamount, which supports a CORK (Hole 1200C) with active fluid discharge. During Expedition 366, we visited Hole 1200C to remove the CORK body. Most of the CORK body from Hole 1200C was removed, leaving the sleeve joint that allows access to the CORK, but it retains the 3.25 inch diameter. Thus, with future funding and ROV operations, a network of four cased borehole observatory systems will exist that span a range of distances from the trench, representing a variety of pressures and temperature conditions at depth and different compositions of deep-sourced fluids. Such a transect will be instrumental to in situ experimentation and future monitoring for the study of, for example, processes associated with material (e.g., rocks, fluid, and mud) flow and alteration (e.g., abiotic and biotic reactions).
