(Submitted February 11, 1999)

Nanocrystalline metals, i.e. metals in which the grain size is in the nanometer range, have a range of technologically interesting properties including increased hardness and yield strength. We present atomic-scale simulations of the plastic behavior of nanocrystalline copper. The simulations show that the main deformation mode is sliding in the grain boundaries through a large number of uncorrelated events, where a few atoms (or a few tens of atoms) slide with respect to each other. Little dislocation activity is seen in the grain interiors. The localization of the deformation to the grain boundaries leads to a hardening as the grain size is increased (reverse Hall-Petch effect), implying a maximum in hardness for a grain size above the ones studied here. We investigate the effects of varying temperature, strain rate and porosity, and discuss the relation to recent experiments. At increasing temperatures the material becomes softer in both the plastic and elastic regime. Porosity in the samples result in a softening of the material, this may be a significant effect in many experiments.

I. INTRODUCTION

The modeling of the mechanical properties of everyday materials is a very challenging problem. The main difficulty is the vastly different length and time scales at which the various processes occur during deformation — ranging from the Ångström and sub-picosecond scales of the atomic processes, to beyond the millimeter and second scales of the macroscopic deformation. Naturally, very different modeling techniques are required to model phenomena at so different scales. Atomic-scale simulations (typically molecular dynamics) can handle time scales of up to a few nanoseconds and system sizes of up to $10^8$ atoms, although one is typically limited to significantly smaller system sizes and simulation times by the available computer resources, and by the need to repeat the simulations at different conditions.

At larger length and time scales, one is forced to abandon the atomistic description of the material. One option is dislocation dynamics, where the fundamental unit of the simulation is the dislocation. The fundamental idea of dislocation dynamics is similar to that of molecular dynamics: by calculating the forces on the dislocation (from the interactions with each other as well as from any applied stress), the equations of motions can be solved numerically. The modeling becomes significantly more complicated than molecular dynamics, mainly because dislocations are lines whereas atoms are points. For that reason, dislocation dynamics is often done in two dimensions, where the dislocations become point defects. A difficulty encountered when the atomic-scale description of the material is abandoned is how to treat inherently atomic-scale processes. In the case of dislocation dynamics, it will mainly be processes such as dislocation annihilation and core effects when the dislocations are intersecting. Parameters describing such processes must be extracted from experiments, or calculated directly using selected atomic-scale simulations.

At still larger length and time scales, continuum models must be used. This will typically be some kind of finite-element based calculation, where the plastic behavior is described by a constitutive relation.

A number of advanced simulation techniques have been proposed, where simulation techniques on several length scales are combined into a single multiscale simulation. Various ways of combining finite element calculations of the long-range elastic fields with atomic-scale simulations of some regions of the material have appeared in the literature. Unfortunately, most of these methods are limited to quasi-static simulations, i.e. to zero temperature.

Various simulation techniques have been proposed to extend the time scales beyond the nanosecond scale reachable by molecular dynamics. Some methods are based on “accelerating” the microscopic dynamics of the system by modifying the potential energy surface (or by extrapolating from higher to lower temperatures). Other methods, such as the “nudged elastic band” method, and constrained molecular dynamics, allow one to determine energy barriers, from which reaction rates of slow processes can be determined.

A different way of addressing the length-scale challenge is by simulating suitably chosen problems, where the characteristic length scale is within the reach of atomic-scale modeling. This has the advantage that the entire problem can be addressed at the atomic scale, removing the need for the \textit{a priori} assumptions about which processes should be included in the simulation — some-
times unexpected atomic-scale processes are seen in such simulations, processes that could not have been included in a coarser-scaled simulation as its importance was not suspected.

One such atomic-scale problem is the mechanical deformation of nanocrystalline metals, i.e. metals where the grain size is in the nanometer range. Nanocrystalline metals have recently received much interest because they may have mechanical, chemical and physical properties different from their coarse-grained counterparts. For example, the hardness and yield stress may increase 5–10 times when the grain size is reduced from the macroscopic to the nanometer range.

Recently, computer simulations of the structure of nanocrystalline metals and semiconductors, and of their elastic and plastic properties have appeared in the literature. In previous papers, we described the plastic deformation of nanocrystalline copper at zero temperature. In this paper we focus on the elastic and plastic properties of nanocrystalline metals, in particular copper, at finite temperature. We find that the materials have a very high yield stress, and that the yield stress decrease with decreasing grain size (reverse Hall-Petch effect). The main deformation mode is found to be localized sliding in the grain boundaries.

The high yield stress and hardness of nanocrystalline metals is generally attributed to the Hall-Petch effect, where the hardness increases with the inverse square root of the grain size. The Hall-Petch effect is generally assumed to be caused by the grain boundaries acting as barriers to the dislocation motion, thus hardening the material. The detailed mechanism behind this behavior is still under debate. A cessation or reversal of the Hall-Petch effect will therefore limit the hardness and strength that can be obtained in nanocrystalline metals by further refining of the grain size. There are a number of observations of a reverse Hall-Petch effect, i.e. of a softening when the grain size is reduced. The interpretation of these results have generated some controversy. It is at present not clear if the experimentally reported reverse Hall-Petch effect is an intrinsic effect or if it is caused by reduced sample quality at the finest grain sizes. The computer simulations presented here show that an intrinsic effect is clearly possible.

The structure of the paper is as follows. In section II we discuss the setup of the nanocrystalline model systems. Section III discusses the simulation and analysis methods used. The simulation results are presented in section IV, and subsequently discussed in section V.

II. SIMULATION SETUP

In order to obtain realistic results in our simulations, and to be able to compare our simulations with the available experimental data, we have attempted to produce systems with realistic grain structures. Unfortunately, the microscopic structure is not very well characterized experimentally, and depends on the way the nanocrystalline metal was prepared. We have tried to create systems that mimic what is known about the grain structure of nanocrystalline metals generated by inert gas condensation. The grains seem to be essentially equiaxed, separated by narrow grain boundaries. The grains are essentially dislocation free. The grain size distribution is log-normal.

A. Construction of the initial configuration

In our simulations, the grains are produced using a Voronoi construction, a set of grain centers are chosen at random, and the part of space closer to a given center than to any other center is filled with atoms in a randomly rotated face-centered cubic (fcc) lattice. Periodic boundary conditions are imposed on the computational cell. This procedure generates systems without texture and with random grain boundaries. Effects of texture could easily be included by introducing preferred orientations of the grains. In the limit of a large number of grains, the Voronoi construction will generate a grain size distribution close to a log-normal distribution.

In the grain boundaries thus generated, it is possible that two atoms from two different grains get too close to each other. In such cases one of the atoms is removed to prevent unphysically large energies and forces as the simulation is started. To obtain more relaxed grain boundaries the system is annealed for 10 000 timesteps (50 ps) at 300 K, followed by an energy minimization. This procedure is important to allow unfavorable local atomic configurations to relax.

To investigate whether the parameters of the annealing procedure are critical, we have annealed the same system for 50 and 100 ps at 300 K, and for 50 ps at 600 K. We have compared the mechanical properties of these systems with those of an identical system without annealing. We find that the annealing is important (the unannealed system was softer), but the parameters of the annealing are not important within the parameter space investigated.

A similar generation procedure has been reported by Chen and D’Agostino and Van Swygenhoven and by Van Swygenhoven and Caro. A different approach was proposed by Phillpot, Wolf and Gleiter: a nanocrystalline metal is generated by a computer simulation where a liquid is solidified in the presence of crystal nuclei, i.e. small spheres of atoms held fixed in crystalline positions. The system was then quenched, and the liquid crystallized around the seeds, thus creating a nanocrystalline metal. In the reported simulations, the positions and orientations of the seeds were deterministically chosen to produce eight grains of equal size and with known grain boundaries, but the method can naturally be modified to allow randomly placed and oriented
seeds. The main drawback of this procedure is the large number of defects (mainly stacking faults) introduced in the grains by the rapid solidification. The stacking faults are clearly seen in the resulting nanocrystalline metal (Fig. 7 of Ref. 27). The appearance of a large number of stacking faults was also seen in the solidification of large clusters even if the cooling is done as slowly as possible in atomistic simulations.

B. Structures

A typical system (after annealing and cooling to zero Kelvin) with a grain size of 5.2 nm is shown in Fig. 1. The atoms have been color coded according to the local crystal structure, as determined by the Common Neighbor Analysis (see section III C). In Figure 2 the radial distribution function (RDBF) g(r) for the same system is shown. It is defined as the average number of atoms per volume at the distance r from a given atom. The RDBF is seen to differ from that of a perfect fcc crystal in two ways. First, the peaks are not sharp delta functions, but are broadened somewhat. This broadening is in part due to strain fields in the grains (probably originating from the grain boundaries), and in part due to atoms in or near the grain boundaries sitting close to (but not at) the lattice positions. The second difference is seen in the inset: the RDBF does not go to zero between the peaks. It is the signature of some disorder which in this case comes from the grain boundaries.

Experimentally, information about the RDBF can be obtained from X-ray absorption fine structure (XAFS) measurements. This method has been used to measure the average coordination number of Cu atoms in nanocrystalline Cu, finding coordination numbers of 11.8 ± 0.3 and 11.9 ± 0.3 in samples with 34 nm and 13 nm grain size, respectively. From these results the average coordination number of the atoms in the grain boundaries was estimated to 11.4 ± 1.2, i.e. within the experimental uncertainty it is the same as in the bulk. Integrating the first peak of the calculated RDBF (Fig. 2) gives an average coordination number of 11.9 ± 0.15. As the RDBF does not go to zero between the first two peaks, it is not clear where the upper limit of the integration should be chosen, hence the uncertainty. The value given is for an upper limit of 3.125 Å. There is thus excellent (but perhaps rather trivial) agreement between the calculated and the experimental coordination numbers.

Numerical studies have shown that the Voronoi construction results in a grain size distribution that it is well described by a log-normal distribution (although for more than 5000 grains a two-parameter gamma distribution gives a better fit). In Fig. 3 we show the grain size distributions in our simulations with intended average grain sizes of 3.28 and 5.21 nanometers. The observed distributions are consistent with log-normal distributions, although due to the rather low number of grains it is not possible to distinguish between a log-normal or a normal distribution.

III. SIMULATION METHODS

We model the interactions between the atoms using a many-body Effective Medium Theory (EMT) potential. EMT gives a realistic description of the metallic bonding, in particular in fcc metals and their alloys. Computationally, it is not much more demanding than pair potentials, but due to its many-body nature it gives a far more realistic description of the materials properties.

The systems can be deformed by rescaling the coordinates along a direction in space (in the following referred to as the z direction). During this deformation either a conventional molecular dynamics (MD) algorithm or a minimization algorithm is used to update the atomic positions in response to the deformation.

In molecular dynamics, the timestep used when integrating the equation of motion must be short compared to the typical phonon frequencies in the system. We use a timestep of 5 fs, safely below the value where the dynamics becomes unstable. A consequence of the short timesteps involved in MD simulations is that only brief periods of time can be simulated. For the size of systems discussed here 1 ns (200000 timesteps) is for all practical purposes an upper limit, although for repeated simulations 0.1 ns is a more realistic limit.

One consequence of the short time-scale is that very high strain rates are required to get any reasonable deformation within the available time, a typical strain rate in the simulations reported here is $5 \times 10^8 \text{s}^{-1}$. This is very high, but still the ends of the system separates at velocities far below the speed of sound. We have investigated the effects of varying the strain rate, see section III B 3.

As another consequence of the short time-scale, slower processes will not be seen in the simulations. In particular, most diffusional processes will be unobservable (this would also be the case in experiments performed at these high strain rates). However, measurements of diffusional creep (Coble creep) in nanocrystalline metals indicate that diffusional creep is not a large effect.

Some of the simulations were performed using a minimization procedure, i.e. the system is kept in a local energy minimum while it is deformed. In such a simulation time is not defined, since we are not solving an equation of motion. In a similar way, time should not be relevant in an experiment performed truly at zero temperature, since there will be no thermally activated processes, and thus no way the sample can leave a local energy minimum (neglecting quantum tunelling). So the strain rate will not have an effect on the results, providing it is low enough to prevent a heating of the sample, and providing the minimization procedure is fully converged. The
minimization simulations can thus be seen as a model for idealized experiments at zero temperature in the low strain rate limit, where there is time for the heat generated by the deformation to be removed.

A. The minimization procedure

To simulate deformation at zero temperature a minimization procedure was used to keep the system in or near a local minimum in energy at all times. The deformation and minimization was done simultaneously. The minimization algorithm is a modified molecular dynamics simulation. After each MD timestep the dot product between the momentum and the force is calculated for each atom. Any atom where the dot product is negative gets its momentum zeroed, as it is moving in a direction where the potential energy is increasing. In this way the kinetic energy of an atom is removed when the potential energy is close to a local minimum along the direction the atom is moving. This minimization procedure quickly brings the system close to a local minimum in energy, but a full convergence is not obtained, as it would require a number of timesteps at least as great as the number of degrees of freedom in the system. However, we find only little change in the development of the system, when we increase the number of minimization steps.

At each timestep the system is deformed by a tiny scaling of the coordinates, the $x$ and $y$ coordinates are multiplied by $1 + \varepsilon$, where $\varepsilon$ is a very small number, chosen to produce the desired deformation rate. The constant $\nu$ is an “approximate Poisson’s ratio”. A Monte Carlo algorithm is used to optimize the two lateral dimensions of the system: after every 20th timestep a change in the lateral dimensions is proposed. If the change result in a reduction of the energy it is accepted, otherwise it is discarded. In this way the kinetic energy of an atom is removed when the potential energy is close to a local minimum along the direction the atom is moving. This minimization procedure quickly brings the system close to a local minimum in energy, but a full convergence is not obtained, as it would require a number of timesteps at least as great as the number of degrees of freedom in the system. However, we find only little change in the development of the system, when we increase the number of minimization steps.

At each timestep the system is deformed by a tiny scaling of the coordinates, the $z$ coordinates are multiplied by $1 + \varepsilon$, the $x$ and $y$ coordinates by $1 - \nu \epsilon$, where $\nu$ is a very small number, chosen to produce the desired deformation rate. The constant $\nu$ is an “approximate Poisson’s ratio”. A Monte Carlo algorithm is used to optimize the two lateral dimensions of the system: after every 20th timestep a change in the lateral dimensions is proposed. If the change result in a reduction of the energy it is accepted, otherwise it is discarded. In this way the exact value chosen for $\nu$ becomes uncritical, as the Monte Carlo algorithm governs the contraction in the lateral directions. The use of $\nu \neq 0$ is just for computational efficiency. We used $\nu = 0.4$ as this was between the optimal value in the part of the simulation where elastic deformation dominates (Poisson’s ratio $\approx 0.3$) and in the part where plastic deformation dominates ($\nu \approx 0.5$ as volume is then conserved).

A few simulations were repeated using a Conjugate Gradient (CG) minimization algorithm instead of the MD minimization algorithm. The two algorithms were approximately equally efficient in these simulations, provided that the CG algorithm was restarted approximately every 20 line minimizations. Otherwise the CG algorithm will not minimize twice along the same direction in the $3N$-dimensional configuration space.

B. Molecular dynamics at finite temperature

At finite temperatures a conventional molecular dynamics algorithm is used, where the Newtonian equations of motion for the atoms are solved numerically. During the simulation the computational box was stretched as described above. The Monte Carlo algorithm optimizing the lateral dimensions is the conventional Metropolis algorithm.

Before the deformation is applied the system is heated to the desired temperature by a short Molecular Dynamics simulations using Langevin dynamics, i.e. where a friction and a fluctuating force is added to the equation of motion of the atoms. When the desired temperature has been reached (after approximately 10 ps), the simulations is performed using the velocity Verlet algorithm. During the deformation process the internal energy increases by the work performed on the system. This amounts in practice to a small heating of the system of the order of $\sim 30$ K.

C. Analysis of the results

While the simulation is performed, the stress field is regularly computed. The stress tensor is the derivative of the free energy of the system with respect to the strain. The effective medium theory allows us to define an energy per atom, which allows us to define an “atomic” stress for each atom. The stress is a suitable derivative of the energy with respect to the interatomic distances.

$$\sigma_{i,\alpha\beta} = \frac{1}{v_i} \left( \frac{p_{i,\alpha} p_{i,\beta}}{m_i} + \frac{1}{2} \sum_{j \neq i} \frac{\partial E_{pot}}{\partial r_{ij}} r_{ij,\alpha} r_{ij,\beta} \right)$$ (1)

where $\sigma_{i,\alpha\beta}$ is the $\alpha, \beta$ component of the stress tensor for atom $i$, $v_i$ is the volume assigned to atom $i$ ($\sum_i v_i = V$, where $V$ is the total volume of the system), $m_i$ is the mass of atom $i$, $p_{i,\alpha}$ is the component of its momentum and $r_{ij}$ is the distance between atoms $i$ and $j$ ($r_{ij,\alpha}$ is a component of the vector from atom $i$ to $j$).

The atomic stress tensor cannot be uniquely defined. Eq. (1) is based on the Virial Theorem, but other definitions are possible. When the atomic stress is averaged over a region of space the various definitions quickly converge to a macroscopic stress field.

During the simulation, stress-strain curves are calculated by averaging the atomic stresses over the entire system. To facilitate the analysis of the simulations the local atomic order was examined using a bond algorithm known as Common Neighbor Analysis (CNA). In this algorithm the bonds between an atom and its neighbors are examined to determine the crystal structure (two atoms are considered to be bonded if they are closer together than a cutoff distance chosen between the first two peaks in the radial distribution function). Bonds are classified
by three integers \((ijk)\). The first integer \(i\) is the number of common neighbors, i.e. atoms bonded to both atoms in the bond under consideration. The second integer \(j\) is the number of bonds between these common neighbors. The third integer \(k\) is the longest chain that can be formed by these bonds.

The number and type \((ijk)\) of bonds that an atom has determines the local crystal structure. For example, atoms in a perfect fcc crystal have 12 bonds of type 421, whereas atoms in a perfect hcp crystal have six bonds of type 421 and six of type 422. In these simulations we have mainly used CNA to classify atoms into three classes: fcc, hcp and “other”, where the “other” class is atoms that have a different number of bonds than 12, or that have bonds that are not of type 421 or 422.

The use of CNA makes dislocations, grain boundaries and stacking faults visible in the simulation. Intrinsic stacking faults appear as two adjacent 111 planes of hcp atoms, extrinsic stacking faults are two 111 planes of fcc atoms, whereas twin boundaries will be seen as a single 111 plane of fcc atoms. Dislocation cores and grain boundaries consist of atoms in the “other” class, although grain boundaries also contain a low number of hcp atoms.

When analyzing simulations made at finite temperatures, the lattice vibrations may interfere with the CNA. For simulations at temperatures up to 300 K it is sufficient to choose the cutoff distance carefully, but for higher temperatures it is necessary to precede the CNA analysis by a short minimization (short enough to remove most of the lattice vibrations, but not long enough to allow dislocations etc. to move). For consistency, such a minimization procedure was used for all finite-temperature simulations regardless of temperature.

### IV. RESULTS

In this section we first discuss the results of the simulations based on the minimization algorithm (i.e. the zero-temperature results), and then we discuss the results obtained using molecular dynamics at finite temperatures.

#### A. Simulations at zero temperature

During the deformation, we calculate the average stress in the system as a function of the strain. Fig. 2 shows the obtained stress-strain curves from simulations at 0 K. We see a linear elastic region followed by a plastic region with almost constant stress. Similar results are found for palladium (Fig. 3). Each stress-strain curve shown in Figs. 2 and 3 are obtained by averaging over a number of simulations with different (randomly produced) grain structures with the same average grain size. A set of stress-strain curves from individual simulations are shown in Fig. 4.

One of the rationales using a minimization procedure to study the deformations was the hope that the system would evolve through a series of local energy minima, separated by discrete events when the applied deformation causes the minima to disappear. In this way, the simulation would have resulted in a unique deformation history for any given sample. However, the deformation turned out to happen through a very large number of very small processes, that could not be individually resolved by this procedure (see below). One symptom of this is, that the individual curves in Fig. 3 are not completely reproducible. Any even minor change in the minimization procedure, or a perturbation of the atomic coordinates, will result in a slightly different path through configuration space, and in different fluctuations in the stress-strain curves. Those differences are suppressed when average stress-strain curves are calculated, as in Fig. 4, and would also disappear as the system size (and thus the number of grains) increase.

1. **Young’s Modulus**

In the linear elastic region the Young’s modulus is found to be around 90-105 GPa and it is increasing with increasing grain size. The experimental value for macrocrystalline copper is 124 GPa at 300 K and the value found for single crystals using this potential is 150 GPa at 0 K (Hill average calculated from the anisotropic elastic constants \(C_{11} = 173\) GPa, \(C_{12} = 116\) GPa, \(C_{44} = 91\) GPa). A similar reduction of Young’s modulus is seen in simulations of nanocrystalline metals grown from a molten phase. The low value is due to the large volume fraction of the atoms being in the grain boundaries. These atoms experience a different atomic environment, which could result in a reduction of the elastic moduli similar to what is seen in amorphous metals. This local reduction of the elastic constants in grain boundaries is confirmed by atomistic simulations.

Experimental measurements of the Young’s modulus of high-quality (i.e. low-porosity) samples of nanocrystalline copper and palladium show a reduction in Young’s modulus of at most a few percent when correcting for the remaining porosity. These results were obtained for significantly larger grain sizes than were used in the simulations. The reduction of Young’s modulus that we observe in these simulation, will be difficult to detect experimentally due to the much lower volume fraction of atoms in the grain boundaries for typical grain sizes in high-quality samples (\(\gtrsim 20\) nm).

2. **Yield and flow stress**

The onset of plastic deformation is usually described by the yield stress \(\sigma_y\), traditionally defined as the stress...
3. Structural changes

Fig. 8 shows the same system as Fig. 1, but after 10% deformation. Some stacking faults have appeared in the grains, they are caused by partial dislocations (Shockley partials) nucleating at the grain boundaries and moving through the grains. One such dislocation is seen in the figure.

The radial distribution function (Fig. 3) has been changed somewhat by the deformation. The peaks have been broadened, this is mainly caused by the anisotropic stress fields in the sample. The “background level” between the first two peaks has increased a little, indicating a larger amount of disorder in the system. Increased disorder is also seen in Fig. 8, where the grain boundaries appear to have become slightly thicker compared to the initial configuration. This is confirmed by Fig. 10, showing the number of atoms in different local configurations before and after the deformation. We see how more atoms are neither fcc nor hcp after the deformation than before.

A strong increase in the number of atoms near stacking faults (atoms in hcp symmetry) is also seen in Figs. 8 and 10. The stacking faults appear as partial dislocations move through the system, and they are thus the signature of dislocation activity. At zero temperature, we do not observe cases where a second partial dislocation erases the stacking faults (we observe only a very few atoms changing from local hcp order to local fcc order). We can therefore use the total number of hcp-ordered atoms to estimate an upper bound on the amount of plastic deformation caused by the dislocations.

If a dislocation with Burgers vector $\vec{b}$ runs through the entire system, the dimensions of the system are changed by $\vec{b}$ and the strain $\varepsilon_{zz}$ is thus $b_z L_z^{-1}$, where $b_z$ is the $z$ component of the Burgers vector and $L_z$ is the dimension of the system in the $z$ direction. If the dislocation only passes through a part of the system, the resulting deformation is reduced by $A \cos \phi (L_x L_y)^{-1}$, where $A$ is the area of the slip, $L_x$ and $L_y$ are the lateral dimensions of the system and $\phi$ is the angle between the slip plane and the $xy$ plane. The contribution from a slip plane to the $zz$ component of the strain is thus $\varepsilon_{zz} = (b_z L_z^{-1}) A \cos \phi (L_x L_y)^{-1}$.

The maximal value of $b_z$ is $b \sin \phi$, where $b = |\vec{b}|$, since $\vec{b}$ lies in the slip plane. The maximal strain from the slip thus becomes $\varepsilon_{\text{max}} = b A (2V)^{-1} = A (2\sqrt{6}V)^{-1}$ for $\phi = \pi/4$, as the Burgers vector of a Shockley partial is $b = a/\sqrt{6}$, where $a$ is the lattice constant and $V$ is the volume of the simulation cell. A slip plane of area $A$ results in two $\{111\}$ planes of hcp atoms, i.e. $4A(\sqrt{3}a^2)^{-1}$ atoms. The total system contains $4V a^{-3}$ atoms, so the fraction of hcp atoms becomes $n = Aa(\sqrt{6}V)^{-1}$. Hence a fraction $n$ of hcp atoms can at most have resulted in a strain of $\varepsilon_{\text{max}} = 2^{-3/2}n$. As the simulation generate at most 9% hcp atoms during 10% deformation, we get that $\varepsilon_{\text{max}} \approx 3\%$, provided that all slip planes and Burgers vectors are ideally aligned. It is therefore clear that the main deformation mode is not by dislocation motion.

Fig. 11 illustrates how the main part of deformation has taken place. The atoms are colored according to their motion relative to the global stretching of the system. We clearly see that the upper parts of the grains have moved down and the lower parts up, relative to what would be expected in a homogeneous deformation. This shows that the grains do not stretch as much as in a homogeneous deformation. On the other hand, it is seen that significant deformation has happened in the grain boundaries, as the atoms typically are moving up on one side and down on the other side of a grain boundary. An analysis of that deformation shows that it is in the form of a large number of apparently uncorrelated small slipping events, where a few atoms (or a few tens of atoms) move relatively to reach other, i.e. not in the form of collective motion in the grain boundaries. A minor part of the plastic deformation is in the form of dislocation motion inside the grains. The slip planes are clearly seen in Fig. 11, in particular in the large grain in the upper left part of the figure, where two dislocations have moved through the grain, and a third is on its way near one of the previous slip planes.

B. Simulations at finite temperature

The simulations were repeated with the same systems (i.e. the same initial grain structure) at finite temperatures. Fig. 12 shows the stress-strain curves for the same system at different temperatures. We clearly see a softening with increasing temperature. Rather large fluctuations are seen in the curves. These are mainly thermal fluctuations and fluctuations due to single major “events” in the systems (e.g. the nucleation of a dislocation). These fluctuations are only visible due to the small system size.

The softening of the material with decreasing grain size is also observed in simulations at 300 K, see Fig. 13.
1. Young’s Modulus

Young’s Modulus ($E$) is the slope of the stress-strain curve in the linear region. When calculating Young’s modulus from the simulation data, a compromise must be made between getting enough data points for a reliable fit, and staying within the clearly linear region. For the zero-temperature simulations, fitting Young’s modulus to the data point for $\varepsilon < 0.1\%$ satisfies both conditions, but for the finite-temperature simulations more data points are required. We have chosen to use data in the interval $\varepsilon < 1\%$, this ensures that we have enough data for a reliable fit, but results in a slight underestimate of the Young’s modulus, as some plastic deformation is beginning in this interval. The results of this procedure is shown in Fig. 14, showing Young’s modulus for a single system with grain size $d = 5.2$ nm, simulated at different temperatures. For consistency, the larger strain interval has been used even for the $T = 0$ simulation. Using the smaller interval ($\varepsilon < 0.1\%$) would result in $E = 119$ GPa instead of $E = 100$ GPa.

The observed temperature dependence of $E$ is approximately -72 MPa/K, which is somewhat larger than what has been observed experimentally (-40 MPa/K) in copper with a grain size of 200 nm. This may be because the Young’s modulus of the grain boundaries is more temperature sensitive than in the bulk, or it may be due to increased creep in the higher-temperature simulations, see the discussion in section IV B 4.

2. Yield and flow stress

The Yield stress is again determined as the stress where the strain is 0.2% above what would be expected from extrapolation from the linear regime. The difficulties leading to an underestimate of the Young’s Modulus thus leads to an overestimate of the yield stress. The values for the yield stress obtained for the simulations at 300 K can therefore not be compared directly with the values obtained at 0 K, but values obtained at different grain sizes can of course be compared, as the same method was used to estimate the yield stress in all cases. The flow stress is a far more well-defined quantity, and direct comparison is possible between simulations at different temperatures. The variation of the yield and flow stresses with temperature is seen in Fig. 14.

Fig. 16 shows the variation of both the yield- and the flow stress with grain size. As in the simulations at 0 K a reverse Hall-Petch relationship is found.

3. Structural changes

The main deformation mode appears to be the same at zero and at finite temperatures. Figure 17 shows the atomic displacements, again the majority of the deformation has taken place in the grain boundaries, only a few slip planes are seen.

The grain boundaries do not appear to increase as much in thickness as they to at 0 K. Fig. 18 shows the change in the fraction of atoms in different local environments during the deformation of the same system at 0 K and at 300 K. In both cases we clearly see an increase in the number of hcp atoms (stacking faults) due to the motion of dislocations through the grains, but the number of atoms in the grain boundaries increases significantly more at 0 K than at 300 K (the increase is approximately twice as big at 0 K as at 300 K). The increase appears to be caused by the deformation in the grain boundaries. Apparently, the local disorder introduced in this way is partially annealed out at 300 K.

4. Strain rate

The finite-temperature simulations presented in this paper were performed at a strain rate of $\dot{\varepsilon} = 5 \times 10^8 s^{-1}$, unless otherwise is mentioned.

In order to investigate the influence of the strain rate, we simulated the same deformation of the same system using different strain rates in the range $2.5 \times 10^7 s^{-1} – 1.0 \times 10^{10} s^{-1}$, see Fig. 19. A strong dependence on the strain rate is seen for strain rates above $1 \times 10^9 s^{-1}$. Below this “critical strain rate” the strain rate dependence on the stress-strain curves is far less pronounced. Fig. 20 confirms this impression. It shows the yield and flow stress as a function of the strain rate. Experiments on ultrafine-grained ($d \approx 300$ nm) Cu and Ni show a clear strain rate dependence on the yield and flow stresses at high strain rates.

Perhaps surprisingly, the Young’s modulus appears to depend on the strain rate as well (Fig. 3). This indicates that some kind of plastic deformation occurs in the “linear elastic” region. This is confirmed by stopping a simulation while the system still appears to be in the elastic region, and then allowing it to contract until the stresses are zero. The system does not regain the original length: plastic deformation has occurred.

To examine the time-scale over which this deformation occurs, a configuration was extracted from the simulation at $\dot{\varepsilon} = 2.5 \times 10^7 s^{-1}$ after 0.4% deformation. The system was held at a fixed length for 300 ps while the stress is monitored, see Fig. 21. The stress is seen to decrease with a characteristic time of approximately 100 ps. By plotting the atomic motion in a plot similar to Figs. 1 and 7, it is seen that the relaxation is due to small amounts of plastic deformation in the grain boundaries. The consequence of this is that the systems do not have time to relax completely during the simulations, explaining the observed strain rate dependence. In order to allow for complete relaxation of the systems, strain rates far below what is practicably possible with MD simulations are
required.

5. Grain rotation

Grain rotation has previously been reported in simulations of nanocrystalline nickel. We have investigated the rotation of the grains during some of the simulations, the results are summarized in Fig. 22. The figure shows the rotation of five randomly selected grains as a function of strain and temperature. The rotations were identified by a three-dimensional Fourier transform of the positions of the atoms in the grains.

We see that the grain rotation increases with increasing temperature. There is a large variation between how much the individual grains rotate. The grains with the largest rotations keep the same axis of rotation during the entire deformation, whereas the grains that only rotate a little have a varying axis of rotation. Probably some grains are in a local environment where a significant rotation results in an advantageous deformation of the sample which reduces the stress. Other grains are randomly rotated as the many small deformation processes in the grain boundaries occur.

6. Porosity

As the observed reverse Hall-Petch effect is often explained as an artifact of sample porosity (see section VA), we found it relevant to study how pores influence the mechanical properties. The void structure in experimentally produced samples is usually not well known, so we chose to study several different types of voids. In all cases the voids resulted in a reduction of both the Young’s modulus and flow stress, see Fig. 23.

Elliptical voids. These crack-like voids were created by removing all atoms within an oblate ellipsoid with an axis ratio of 3.16. The short axis can be oriented along the pulling direction (the \(z\)-axis) or perpendicular to it (the \(x\)-axis). The former orientation corresponds to cracks that are activated by the applied stress field, the effect of these cracks is therefore expected to be much larger than the effect of the “inactive” cracks. This is clearly seen in Fig. 23.

Missing grains. There have been reports of pore sizes comparable to (and proportional to) the grain size. To emulate this, we have tried to remove whole grains from the system. As the grains are approximately equiaxed, it is not surprising that the effect of removing a grain is intermediate between the effects of removing ellipsoids in the two orientations, provided that approximately the same number of atoms is removed.

Missing grain boundary atoms. In samples experimentally produced by compacting a powder, it is reasonable to assume that the porosity will mainly be in the form of (possibly gas-filled) voids between the grains. There is also some experimental evidence that this is indeed the case. To emulate this, we have removed all atoms in the grain boundaries within one or nine spherical regions in the sample, creating one large or nine small voids in the grain boundaries. This type of voids have the largest effect on the materials properties, giving a reduction of 35–40% in the Young’s modulus and flow stress for a 12.5% porosity. It seems rather natural that a large effect is obtained with the voids concentrated in the grain boundaries since we know that the main part of the deformation is carried by these boundaries.

V. DISCUSSION

A. The reverse Hall-Petch effect

A reverse Hall-Petch effect in nanocrystalline copper was first observed in nanocrystalline Cu and Pd by Chokshi et al. in 1989. Since then, there have been numerous observations of softening at very small grain sizes.

The reverse Hall-Petch effect seems to depend strongly on the sample preparation technique used and on the sample history, perhaps indicating that in most cases the reverse Hall-Petch effect is caused by various kinds of defects in the samples. Surface defects alone have been shown to be able to decrease the strength of nanocrystalline metals by a factor of five and recent studies have shown that even very small amounts of porosity can have a dramatic effect on the strength. Improved inert gas condensation techniques have reduced the porosity resulting in samples with densities above 98% of the fully-dense value. In these samples the ordinary Hall-Petch effect is seen to continue down to grain sizes around 15 nm. There are only few data points below that grain size, but apparently no further increase in the hardness is seen. It is suggested that most of the observations of a reverse Hall-Petch effect in nanocrystalline metals are a result of poor sample quality.

This impression is supported by literature studies, indicating that the reverse Hall-Petch effect is mainly seen when the grain size is varied by repeated annealing of a single sample, whereas an ordinary Hall-Petch relationship is seen when as-prepared samples are used.

However, there does seem to be a deviation from the Hall-Petch effect for grain sizes below approximately 15 nm, where the Hall-Petch slope is seen to decrease or vanish in samples produced with various techniques. This is seen in Cu samples produced by inert gas condensation followed by warm compaction (sample densities above 98%) and in electroplated Ni (claimed to be porosity free).

There are theoretical arguments for expecting that the Hall-Petch relation ceases to be valid for grain sizes below ~20 nm: as the grain size becomes too small, dislocation pileups are no longer possible, and the usual explanation for Hall-Petch behavior does not apply.
Many models have been proposed to explain why a reverse Hall-Petch effect is sometimes seen. Chokshi et al. proposed that enhanced Coble creep, i.e. creep by diffusion in the grain boundaries, should result in a softening at the smallest grain sizes as the creep rate increases with decreasing grain size \( d \). Direct measurements of the creep rate have however ruled this out.

It has been suggested that the grain boundaries in nanocrystalline metals have a different structure, making them more transparent to dislocations than “ordinary” grain boundaries. If it becomes possible for the dislocations to run through several grains as the grain size is reduced, the Hall-Petch relations would break down. In our simulations, we have not observed dislocations moving through more than one grain.

If the Hall-Petch effect is explained by appealing to dislocation sources in the grain boundaries, the Hall-Petch relationship is expected to break down when the grain sizes becomes so low that there are no longer dislocation sources in all grain boundaries (assuming a constant density of dislocation sources in the grain boundaries).

Hahn et al. suggest that the reverse Hall-Petch effect is caused by deformation in the grain boundaries. If a grain boundary slides, stress concentrations build up where the grain boundary ends, limiting further sliding. Substantial sliding on a macroscopic scale occurs when sliding occurs on slide planes consisting of many aligned grain boundaries; the sliding is hindered by the roughness of the slide plane due to its consisting of many grain boundaries. As the grain size is reduced and becomes comparable to the grain boundary width, the roughness of such slide planes decreases and the stress required for mesoscopic sliding decreases. This would result in a reverse Hall-Petch effect. They estimate the transition from normal to reverse Hall-Petch effect to occur at grain sizes near 50 nm for Cu.

The simulations reported in the present paper indicate that the main deformation mechanism at these grain sizes is indeed sliding in the grain boundaries. However, it is not clear if the proposed “collective” sliding events are occurring, it appears that sliding occurs on individual grain boundaries, and that the resulting stress buildup is relieved through dislocation motion in the grains. There is a competition between the ordinary deformation mode (dislocations) and the grain boundary sliding. As the grain size is increased, the dislocation motion is eventually expected to dominate, and we expect a transition to a behavior more like what is seen in coarse-grained materials, incl. a normal Hall-Petch effect. The transition is beyond what can currently be simulated at the atomic scale, but we do see a weak increase in the dislocation activity when the grain size is increased: The increase in the fraction of hcp atoms during a simulation is increasing slightly with the grain size (Fig. [Fig.]).

VI. CONCLUSIONS

Molecular dynamics and related techniques have been shown to be a useful approach to study the behavior of nanocrystalline metals. We have in detail investigated the plastic deformation of nanocrystalline copper, and shown that the main deformation mode is sliding in the grain boundaries. The sliding happens through a large number of small, apparently uncorrelated events, where a few grain boundary atoms (or a few tens of atoms) move past each other. It remains the main deformation mechanism at all grain sizes studied (up to 13 nm), even at zero temperature. As the grain boundaries are the main carriers of the deformation, decreasing the number of grain boundaries by increasing the grain size leads to a hardening of the material, a reverse Hall-Petch effect. This is observed in the simulations, both for \( T = 0K \) and for \( T = 300K \).

The Young’s moduli of the nanocrystalline systems are found to be reduced somewhat compared to the experimental value for polycrystalline copper with macroscopic grain sizes, decreasing with decreasing grain size. This indicates that the grain boundaries are elastically softer than the grain interiors. The Young’s modulus is decreasing with increasing temperature at a rate somewhat above what is seen experimentally in coarser-grained copper.

Pores in the samples have a large effect on both the Young’s modulus and the flow stress. This effect is enhanced if the pores are mainly in the grain boundaries, as one could expect in samples produced experimentally by inert gas condensation. Sample porosity can explain a large number of experiments showing reverse Hall-Petch effect, but the softening due to grain boundary sliding may be important for high-quality samples with grain sizes close to the lower limit of what can be reached experimentally.

FIG. 1. The initial configuration of a nanocrystalline copper system. The system contains approximately 100,000 atoms arranged in 16 grains, giving an average grain diameter of 5.2 nm. Atoms are color-coded according to the local crystalline order. White atoms are in a perfect fcc environment. Green atoms are in local hcp order, which for example corresponds to stacking faults. Atoms in any other environment (in grain boundaries and dislocation cores) are colored purple.
FIG. 2. The radial distribution function $g(r)$ for the system in Fig. 1 at $T = 0$. It is the average number of atoms per volume at the distance $r$ from a given atom. The marks above the peaks indicate the positions of the (infinitely sharp) peaks in a perfect crystal at $T = 0$. The inset shows that $g(r)$ does not vanish between the first and second peak as it does for a perfect crystal. This contribution comes from the grain boundaries.

FIG. 3. The grain size distributions obtained from the Voronoi construction. Grain size distributions are shown for simulations with intended average grain sizes of 3.28 and 5.21 nm. In both cases the input configurations from four simulations were used to calculate the distributions. Fits to log-normal (solid) and normal (dashed) distributions are shown. Both distributions fit the data well.

FIG. 4. Stress-strain curves for nanocrystalline copper at 0 K. Each curve is the average over seven simulations with a given average grain size, the error bars indicate the uncertainty of the average ($1\sigma$). Adapted from Ref. 33.

FIG. 5. Stress-strain curves for nanocrystalline palladium at 0 K. Each curve is the average over two simulations with a given average grain size.
FIG. 6. Individual stress-strain curves for seven simulations of nanocrystalline copper with an average grain size of 5.21 nm.

FIG. 7. Hall-Petch plot of the simulations at 0 K, showing a reverse Hall-Petch relationship between the grain size and both the yield- and flow stress.

FIG. 8. The final configuration of the nanocrystalline copper system shown in Fig. 1 after 10% deformation. Some stacking faults have appeared where partial dislocations have moved through the grains. The arrow marks a partial dislocation on its way through the grain.

FIG. 9. The radial distribution function for the system in Fig. 8 at $T = 0$. The marks above the peaks indicate the peak positions in a perfect fcc crystal.
FIG. 10. The fraction of atoms in a given local crystal structure as a function of the grain size. Two curves are given for each type of atoms, one for the initial configurations (filled circles) and another showing how the fractions have changed after 10% deformation (open squares). We see how the fraction of atoms in the grain boundaries (marked “Other”) decreases with increasing grain size, and how more atoms are in grain boundaries and stacking faults (hcp) after the deformation than before.

FIG. 11. The same system as in Fig. 8, but with the atoms colors according to their motion relative to the homogeneous deformation. Blue atoms have moved downwards relative to what would be expected if the deformation had been homogeneous and elastic; red atoms have moved upwards. The scale indicate how far the atoms have moved (in Ångström) during the 10% deformation. The grains are seen to be blue in the upper part, and red in the lower part, indicating that the grains have not been strained as much as the system. This indicates, that a major part of the deformation has been in the grain boundaries. Several dislocations have moved through the large grain in the upper-left corner. Their slip planes are clearly seen.

FIG. 12. Stress-strain curves for the system in Fig. 8, deformed at different temperatures. The strain rate (\dot{\varepsilon}) is $5 \times 10^8 \text{s}^{-1}$ except at 0 K, where no strain rate can be defined (see text). We see a clear softening at increasing temperatures.
FIG. 13. Stress-strain curves for nanocrystalline copper at 300 K for varying grain size. The curves for grain sizes $d \leq 5.21 \text{ nm}$ are the average of four simulations with a system size of 100 000 atoms and a strain rate of $5 \times 10^8 \text{s}^{-1}$. The simulations with $d \geq 6.56 \text{ nm}$ were made with a system size of 1 000 000 atoms and a strain rate of $10^9 \text{s}^{-1}$. The influence of this change in the strain rate is minimal, see section IV B 4 and Fig. 19. One simulation was performed with $d = 6.56 \text{ nm}$, two with $d = 13.2 \text{ nm}$. The thermal fluctuations are less pronounced in the simulations with the larger system size.

FIG. 14. Young’s modulus as a function of temperature for a sample with an average grain size of 5.2 nm.

FIG. 15. Yield and flow stresses as a function of temperature. No yield stress is given for $T = 0 \text{K}$, as the yield stress at this temperature cannot directly be compared to that at finite temperatures, see section IV B 1.

FIG. 16. A Hall-Petch plot of the simulations at 300K. As at 0K, a reverse Hall-Petch relation is seen.
FIG. 17. The same system as in Fig. [1], but after deformation at 300 K, see the caption of that figure for a description of the color coding. The main deformation is seen to be in the grain boundaries, as was the case at 0 K.

FIG. 18. Development of the number of atoms in different local environments as a function of the strain, for a single simulation at 0 K and at 300 K.

FIG. 19. The effect of varying the strain rate. Stress-strain curves are shown for simulations of the same system at the same temperature (300 K), but with varying strain rates. A strong influence of strain rate is seen for strain rates above $\dot{\varepsilon} = 10^9 \text{s}^{-1}$, below that value the strain rate dependence is less pronounced. The simulations at the two lowest strain rates were stopped after 4% deformation.

FIG. 20. Summary of the effect of varying the strain rate. Both the yield stress and the flow stress are seen to vary with the strain rate ($\dot{\varepsilon}$), strongest for $\dot{\varepsilon} > 10^9 \text{s}^{-1}$. 

16
FIG. 21. Sample relaxation in the “elastic” region. The deformation is stopped after 0.4% deformation at \( \dot{\varepsilon} = 2.5 \times 10^7 \, s^{-1} \) and \( T = 300K \). The stress is seen to decrease with a characteristic time of \( \sim 100 \, ps \), stabilizing on a value of \( 2/3 \) the original stress. The thick black line is an exponential fit.

FIG. 22. Grain rotation as a function of strain and temperature. The rotation of five randomly selected grains were followed in simulations at different temperatures. The average grain size is 5.2 nm. The error bars indicate the 1\( \sigma \) spread in the rotations.

FIG. 23. Effect of voids on the Young’s Modulus (top) and on the flow stress (bottom), showing a decrease of both quantities with increasing void fraction. The voids were generated by removing selected atoms, the “void fraction” is the fraction of atoms removed. Different methods were used to select the atoms to be removed, see section IV B 6.
