Abstract: Electromagnetic form factors are fundamental quantities describing the internal structure of hadrons. They can be measured with scattering processes in the space-like region and annihilation processes in the time-like region. The two regions are connected by crossing symmetry. The measurements of the proton electromagnetic form factors in the time-like region using the initial state radiation technique are reviewed. Recent experimental studies have shown that initial state radiation processes at high luminosity electron-positron colliders can be effectively used to probe the electromagnetic structure of hadrons. The BABAR experiment at the B-factory PEP-II in Stanford and the BESIII experiment at the τ-charm factory BEPCII in Beijing have measured the time-like form factors of the proton using the initial state radiation processes e+e− → p̅pγ. The two kinematical regions where the photon is emitted from the initial state at small and large polar angles have been investigated. In the first case the photon is in the region not covered by the detector acceptance and is not detected. The Born cross section and the proton effective form factor have been measured over a wide and continuous range of the momentum transfer squared q 2 from threshold up to 42 (GeV/c) 2. The ratio of electric and magnetic form factors of the proton has been also determined. In this report, the theoretical aspect and the experimental studies of the initial state radiation process e+e− → p̅pγ are described. The measurements of the Born cross section and the proton form factors obtained in these analyses near the threshold region and in the relatively large q 2 region are examined. The experimental results are compared to the predictions from theory and models. Their impact on our understanding of the nucleon structure is discussed.

Keywords: proton, electromagnetic form factors, initial state radiation, time-like

1. Introduction

The concept of symmetry plays a key role for understanding the fundamental building blocks of the universe and the forces binding them. Experiments employing antimatter, a mirror or a counterpart of a subatomic particle with opposite charge and right- or left-handed spin, provide important information about the elementary units of which the universe is composed. Measurements of the exclusive production of hadron pair in electron positron annihilation for example are of great interest for understanding the internal structure of hadrons. Assuming the exchange of a virtual photon of positive momentum transfer squared, q 2, between the initial and the final states, these processes contain direct information on the electromagnetic form factors (EMFFs) in the time-like region. The number of independent EMFFs is determined by the spin of the hadron taking into account symmetry properties of the electromagnetic interaction under the Charge, Parity, and Time (CPT) transformations. Spin 1/2 baryons are characterized by the electric form factor G E(q 2) and magnetic form factor G M(q 2). In the space-like region (q 2 < 0), the EMFFs for stable baryons are experimentally accessible.

through the measurements of cross sections for elastic electron baryon scattering. The crossed symmetry channels $e^+e^- \rightarrow B\bar{B}$ allow to access the Time-Like region. Crossing symmetry, which holds at the tree level, states that the same amplitude describes the crossed processes, which occur in different kinematical regions, and connect the time-like with the space-Like EMFFs. In the $e^+e^-$ experiments, time-like EMFFs have been measured using the so-called energy scan technique, in which the center of mass (c.m.) energy ($\sqrt{s}$) of the collider is varied systematically, and at each c.m. energy point a measurement of the associated cross section is carried out through the $e^+e^-$ direct annihilation process. This method, however, can not be used at $e^+e^-$ colliders that are designed to operate at fixed c.m. energies such as the $B$-factories PEP-II at SLAC and KEK-B in Tsukuba with a $\sqrt{s}$ corresponding to the mass of the $\Upsilon(4S)$-resonance. A complementary approach to the energy scan technique that allows the measurements of the hadronic final states with invariant masses below the c.m. energy of the collider is provided by the initial state radiation (ISR) method. The ISR method, also called radiative return technique, employs measurements the process $e^+e^- \rightarrow \text{hadrons} + n\gamma$ where the emission of one or more high energy photons reduces the mass squared of the hadronic system to below $\sqrt{s}$.

The theoretical studies of the ISR processes started long time ago in the sixties of the $20^{th}$ century. The importance of the ISR approach has been outlined in the calculation of the photon emission for muon pair production in Ref. [1] and for pions in Ref. [2]. The possibility of using this approach at the high luminosity $e^+e^-$ colliders has been discussed later [3–6], in particular when the first generation of $\Phi$ and $B$ factories came in operation in the late nineties. It has been realized that the suppression factor $\alpha/\pi$, where $\alpha$ is the fine electromagnetic constant, due to the photon emission can be well compensated by the high luminosities collected at the $e^+e^-$ facilities, providing precise measurements of hadronic final states over a wide c.m. energy range. In addition, this method provides a great control of systematic effects since only one experimental setup is involved in this wide range coverage.

The ISR approach became a powerful tool for the analysis of experiments after the development of dedicated Monte Carlo event generators for the ISR processes, including higher order QED corrections, such as the PHOKHARA event generator [7,8] and the AFKQED package (based on an early version of PHOKHARA called EVA [5,9]). The theoretical studies of the ISR processes started long time ago in the sixties of the $20^{th}$ century. The importance of the ISR approach has been outlined in the calculation of the photon emission for muon pair production in Ref. [1] and for pions in Ref. [2]. The possibility of using this approach at the high luminosity $e^+e^-$ colliders has been discussed later [3–6], in particular when the first generation of $\Phi$ and $B$ factories came in operation in the late nineties. It has been realized that the suppression factor $\alpha/\pi$, where $\alpha$ is the fine electromagnetic constant, due to the photon emission can be well compensated by the high luminosities collected at the $e^+e^-$ facilities, providing precise measurements of hadronic final states over a wide c.m. energy range. In addition, this method provides a great control of systematic effects since only one experimental setup is involved in this wide range coverage.

The ISR approach became a powerful tool for the analysis of experiments after the development of dedicated Monte Carlo event generators for the ISR processes, including higher order QED corrections, such as the PHOKHARA event generator [7,8] and the AFKQED package (based on an early version of PHOKHARA called EVA [5,9]). The theoretical accuracy and the flexibility provided by these event generators have allowed experiments like BABAR, Belle, KLOE and BESIII to simulate a large number of hadronic reactions and perform precise measurements of the corresponding cross sections.

In the time-like region, Measurements of baryon EMFFs using the ISR technique have been provided by BABAR, Belle and BESIII experiments. The BABAR experiment at PEP-II [10] has measured the time-like EMFFs of the proton with the ISR process $e^+e^- \rightarrow p\bar{p}\gamma$ [11–13] using data sets of integrated luminosity up to 469 fb$^{-1}$. The two kinematical regions where the photon is emitted from the initial state at small and large polar angles have been investigated. In the first case, the small angle ISR (SA-ISR, also called ISR-Untagged), the photon is in the region not covered by the detector acceptance and is not detected, while in the second case for the large angle ISR (LA-ISR, also called ISR-Tagged), the photon has to be detected and all the particles in the final state are fully reconstructed. The Born cross section and the proton effective form factor have been measured over a wide and continuous range of the the momentum transfer squared $q^2$ from threshold up to 42 (GeV/c)$^2$ considering both analyses. The ratio of electric and magnetic form factors of the proton has been also determined in the LA-ISR analysis. The hyperon final states $\Lambda\Lambda\gamma$, $\Lambda\Sigma^0\gamma$, $\Sigma\Sigma^0\gamma$ have been also investigated by BABAR [14]. The $|G_E/G_m|$ ratio for the $\Lambda$ hyperon has been measured in two mass intervals between 2.23 and 2.80 GeV/c$^2$. The Belle collaboration at KEK-B used the ISR-technique in the charmonium energy region and measured the process $e^+e^- \rightarrow \Lambda_c^+\Lambda_c^-$ [15]. The BESIII experiment in Beijing provided the world’s largest samples of $e^+e^-$ collisions in the $\tau$-charm region. Large data samples have been accumulated at c.m. energies corresponding
to the charmonium and $X$, $Y$ and $Z$ states. At $\sqrt{s}=3.773$ GeV, an integrated luminosity of 2.9 fb$^{-1}$ has been accumulated and used for most of the ISR analyses. Using these data samples, precise measurements of the proton EMFFs have been performed with the ISR method [16,17]. Both LA- and SA-ISR approaches have been studied at BESIII.

Important results with the ISR technique have been also obtained for mesonic final states. Precise measurements, for example, on the cross section for the processes $e^+e^- \rightarrow \pi^+\pi^-$ and $e^+e^- \rightarrow K^+K^-$ have been provided by KLEO, BABAR, and BESIII experiments [18–25]. These measurements cover a wide mass range and have a large impact on the calculation of the hadronic contribution to the anomalous magnetic moment of the muon.

In this report, we describe the ISR analyses for the proton EMFFs measurements at BABAR and BESIII experiments. In section 2, the theoretical calculations of the differential and integrated cross section for the process $e^+e^- \rightarrow p\bar{p}\gamma$ are described. The experimental results of the proton EMFFs measurements from both experiments are reviewed in section 3, and following by a discussion in section 4.

2. Theoretical description for the process of $e^+e^- \rightarrow p\bar{p}\gamma$

2.1. Born cross section for $e^+e^- \rightarrow p\bar{p}$ process

![Feynman diagram](image)

**Figure 1.** Feynman diagram for the process of $e^+e^- \rightarrow p\bar{p}$ under the assumption of one virtual photon exchange. The bold vertex provides access to the hadronic FFs information.

In the $e^+e^-$ c.m. frame, the differential cross section for the process of $e^+e^- \rightarrow p\bar{p}$ under the assumption of one virtual photon exchange (Fig. 1) is [26],

$$
\frac{d\sigma_{p\bar{p}}(q^2)}{d\cos\theta_p} = \frac{\pi\alpha^2\beta C}{2q^2} \left[ |G_M(q^2)|^2 \left( 1 + \cos^2\theta_p \right) + \frac{|G_E(q^2)|^2}{\tau} \sin^2\theta_p \right],
$$

(1)

where $q^2$ is equal to the square of the $p\bar{p}$ invariant mass $M_{p\bar{p}}$, $\alpha \approx \frac{1}{137}$ is the fine structure constant, $\beta = \sqrt{1-1/\tau}$ is the velocity of the proton with $\tau = q^2/4m_p^2$ and $m_p$ the proton mass, and $\theta_p$ is the polar angle of the proton in the $e^+e^-$ c.m. frame where the $z$-axis points along the direction of the positron momentum. The Coulomb factor $C = \frac{y}{1-\epsilon\tau}$ with $y = \frac{n_p}{n_e}$ accounts for the electromagnetic interaction between the outgoing proton and antiproton [12,27]. The cross section depends on the moduli of the magnetic and electric FFs, which can be determined from the analysis of the proton angular distribution. By integrating the differential cross section (Eq. (1)), the total cross section for the process $e^+e^- \rightarrow p\bar{p}$ is obtained,

$$
\sigma_{p\bar{p}}(q^2) = \frac{4\pi\alpha^2\beta C}{3q^2} \left[ |G_M|^2 + \frac{|G_E|^2}{2\tau} \right].
$$

(2)

An effective form factor can be introduced as a combination of $|G_M|^2$ and $|G_E|^2$,

$$
|G_{\text{eff}}| = \sqrt{\frac{2\tau|G_M|^2 + |G_E|^2}{2\tau + 1}},
$$

(3)

which is equivalent to $|G_M|$ determined from Eq. 2 under the assumption of $|G_M| = |G_E|$. 

2.2. Cross section for the $e^+ e^- \rightarrow p \bar{p} \gamma$ process

The cross section for the lowest order ISR process shown in Fig. 2, i.e. including only one photon emission from the initial state and integrated over the proton momenta, can be written as [5,11,28],

$$\frac{d\sigma_{p\bar{p}\gamma}(q^2)}{dq^2 \cos \theta_\gamma^*} = \frac{1}{s} W(s, x, \theta_\gamma^*) \sigma_{p\bar{p}}(q^2),$$  \hspace{1cm} (4)

$$x = \frac{2E_\gamma}{\sqrt{s}} = 1 - \frac{q^2}{s},$$

where $E_\gamma$ and $\theta_\gamma^*$ are the energy and the polar angle of the ISR photon, respectively, in the $e^+ e^-$ c.m. frame. This procedure allows for the convolution incorporated in event generators and applied to the experimental analyses taking into account the conditions of these experiments. This procedure allows for the convolution

$$\int d\omega \int d\hat{p}_\gamma \left| G_{E} \right|^2 \left| G_{M} \right| \cos \theta_p,$$

where $\omega$ is the photon energy and $\theta_p$ is the angle between the proton in the $p \bar{p}$ rest system and the momentum of the $p \bar{p}$ system in the $e^+ e^-$ c.m. frame.

\[\]  \hspace{1cm} (5)

where $m_e$ is the electron mass. The integration of $W(s, x, \theta_\gamma^*)$ over the ISR photon angle is given for two practically cases [28,29]. The first one is given for a range of integration $\theta^0_\gamma < \theta^*_\gamma < (\pi - \theta^0_\gamma)$ and $\theta^0_\gamma \gg m_e/\sqrt{s}$,

$$W(s, x) = \frac{\alpha}{\pi x} \left[ 2 - 2x + x^2 \right] \ln \frac{1 + \cos \theta^0_\gamma}{1 - \cos \theta^0_\gamma - x^2},$$  \hspace{1cm} (6)

For the full range of the ISR polar angle ($\theta^0_\gamma = 0$),

$$W(s, x) = \frac{\alpha}{\pi x} \left( \ln \frac{s}{m^2_e} - 1 \right) \left( 2 - 2x + x^2 \right).$$  \hspace{1cm} (7)

\[\]

\[\]

\[\]

\[\]

For the full range of the ISR polar angle ($\theta^0_\gamma = 0$),

$$W(s, x) = \frac{\alpha}{\pi x} \left( \ln \frac{s}{m^2_e} - 1 \right) \left( 2 - 2x + x^2 \right).$$  \hspace{1cm} (7)

between the radiative corrections and the corrections of other experimental factors like for example the detection efficiency and the acceptance.

In the simulations of the $e^+e^- \rightarrow p\bar{p}\gamma$ process at large photon emission angle, the BABAR collaboration has considered the additional photon radiation from the initial state using the structure function method [31,32]. This correction takes into account soft multi-photon emission and $\alpha^2$ terms in the leading logarithmic calculations. The radiative correction factor calculated by BABAR includes initial state radiation and the effect of loops at the electron vertex, but does not include corrections for leptonic and hadronic vacuum polarization in the photon propagator.

The BESIII collaboration used the radiative correction calculations provided by the PHOKHARA event generator. The full next-to-leading (NLO) order QED corrections to ISR in the process $e^+e^- \rightarrow \gamma + \text{hadrons}$, where $\gamma$ is emitted at non vanishing angle relative to the electron or positron beams, is considered in Ref. [8]. This includes virtual and soft photon corrections to the process $e^+e^- \rightarrow \gamma + \text{hadrons}$ and the emission of two real hard photons $e^+e^- \rightarrow \gamma + \gamma + \text{hadrons}$. These calculations have been extended in Refs. [33,34] to the collinear region where the photons can be emitted at large and small angles relative to the electron or positron beams. The contribution of the leptonic and hadronic vacuum polarization in the virtual photon line has also been taken into account [35]. The influence of final state radiation has been investigated in Ref. [36].

3. Experimental results of proton form factors from ISR process

The proton EMFFs have been measured through the ISR technique at BABAR and BESIII experiments, with both SA- and LA-ISR photon kinematic ranges.

3.1. ISR process $e^+e^- \rightarrow p\bar{p}\gamma$ at BABAR and BESIII experiments

The BABAR experiment started to take physics data in October 1999 and completed data taking in April 2008. Analyses through the ISR process were performed for the full data\(^1\) with an integrated luminosity of 469 fb\(^{-1}\), which were collected at an c.m. energy of 10.58 GeV ($\Upsilon(4S)$) and 10.54 GeV for about 90% and 10%, respectively [12,13]. Depending on whether the ISR photon is detected within the detection volume or escapes through the beam pipes, the analyses are referred to as LA-ISR or SA-ISR, respectively. The event selection for both types of analyses requires that two charged tracks originating from the interaction region are detected and identified as a proton or antiproton. For the LA-ISR analysis, additional photons have to be reconstructed in the events and a four-momentum kinematic fit is applied for the proton, antiproton and most-energetic photon. For the SA-ISR analysis, a requirement on $p\bar{p}$ transverse momentum is applied to remove the LA-ISR events and to suppress the background events. Figure 3 shows the $p\bar{p}$ invariant mass distribution from the LA-ISR and SA-ISR analyses.

---

\(^1\) BABAR experiment has performed the LA-ISR analysis with half of luminosity, 232 fb\(^{-1}\), in 2006 [11]. In this report, the results from BABAR LA-ISR analysis with the full data sets [12] are reviewed.
Two ISR analyses (SA-ISR and LA-ISR) were performed at the BESIII experiment for the proton EMFFs measurements by using data sets collected at seven c.m. energies between 3.773 and 4.600 GeV with a total integrated luminosity of 7.5 fb$^{-1}$ [16,17]. Similar to the BABAR experiment, both analyses required that two charged tracks, generated from the interaction region, are identified as a proton and an antiproton. For the LA-ISR analysis, an additional most-energetic photon is included together with the proton and antiproton for a four-momentum kinematic fit to suppress the background. The dominant background is from the $e^+e^- \rightarrow pp\pi^0$ process with one photon from the $\pi^0$ decay misidentified as the ISR photon. For the SA-ISR analysis, the ISR photon escapes through the beam pipes and consequently, requirements on the missing momentum and missing mass squared of the proton and antiproton system are used to further suppress background such as two-photon, $pp\pi^0$ and higher order ISR processes. Figure 4 shows the $p\bar{p}$ invariant mass spectra from BESIII LA-ISR (a) and SA-ISR (b) analyses.

The Born cross section of $e^+e^- \rightarrow p\bar{p}$, the proton effective form factor and the ratio of the proton EMFFs were measured at different $p\bar{p}$ invariant mass region for the LA- and SA-ISR analyses from both BABAR and BESIII experiments, and Tab. 1 summarizes the information of the four analyses.
Table 1: Information of the proton EMFFs measurements with LA- and SA-ISR analyses at BABAR and BESIII experiments.

| Experiment                | \(\sqrt{s}\) (range) [GeV] | \(L_{int}\) [fb\(^{-1}\)] | \(\sqrt{q^2}\) range [GeV/c\(^2\)] | total events |
|---------------------------|-----------------------------|-----------------------------|-------------------------------------|--------------|
| BABAR LA-ISR             | 10.58                       | 469                         | 1.877 - 4.5, 1.877 - 3.0            | 6876.0 \(\pm\) 107.2 |
| BABAR SA-ISR             |                             |                             | 3.0 - 6.5                           | 140.0 \(\pm\) 13.2 |
| BESIII LA-ISR            | 3.773 - 4.60                | 7.5                         | 1.876 - 3.0, 2.0 - 3.8, 3.0 - 6.5   | 2952.2 \(\pm\) 75.4 |
| BESIII SA-ISR            |                             |                             | 2.0 - 3.8, 2.0 - 3.0, 2.0 - 3.8, 3.0 - 6.5 | 6714.2 \(\pm\) 87.4 |

3.2. Born cross section of \(e^+e^- \rightarrow p\bar{p}\) and proton effective FF

The Born cross section of \(e^+e^- \rightarrow p\bar{p}\) is calculated in small \(p\bar{p}\) invariant mass intervals,

\[
\sigma_{p\bar{p}}(m_{p\bar{p}}) = \frac{N_{p\bar{p}}}{\epsilon_i (1 + \delta_i) L_i} \tag{8}
\]

where the superscript \(i\) represents the \(i^{th}\) \(p\bar{p}\) mass interval, \(N_{p\bar{p}}^i\) is the number of \(p\bar{p}\) events, \(\epsilon_i\) and \(1 + \delta_i\) are the detection efficiency and the radiative correction factor determined by the MC simulation, and \(L_i\) is the ISR differential luminosity calculated as,

\[
L_i = \int W(s, x) L dx, \quad x = 1 - \frac{q^2}{s}, \tag{9}
\]

where \(q^2\) is the four momentum transfer squared for the \(i^{th}\) \(p\bar{p}\) mass interval. In BABAR LA-ISR analysis, the process of \(e^+e^- \rightarrow p\bar{p}\gamma\) is simulated to extract the selection efficiency and radiative correction factor at the range: \(20^\circ < \theta_\gamma^i < 160^\circ\) in the \(e^+e^-\) c.m. frame, therefore a reduced phase-space factor \(\cos \theta_\gamma^i\) with \(\theta_\gamma^i = 20^\circ\) was included to calculate the differential luminosity by using the equation \(6\) \[11,12\]. In both analyses from the BESIII experiment, the full radiative function \(W(s, x)\) (Eq. 7) was used for the differential luminosity calculation, since the process was simulated in a full phase space \[16,17\]. The analyses from BESIII experiment contain data sets from seven c.m. energies with different integrated luminosity, the differential luminosity was calculated from each data set and summed up together. To determine the MC efficiency and the radiative correction factor, their mean value was calculated from all the MC simulations from seven c.m. energies.

![Figure 5](image_url)

**Figure 5.** The cross section for the process \(e^+e^- \rightarrow p\bar{p}\) (a) and the effective FF of the proton (b) \[17\]. The experimental data presented also include measurements from direct annihilation process.

The effective form factor of the proton is extracted from the \(e^+e^- \rightarrow p\bar{p}\) cross section measurements for both LA- and SA-ISR analyses at BABAR and BESIII experiments according to Eq. 2 and 3. Figure 5 shows the results for the \(e^+e^- \rightarrow p\bar{p}\) cross section (Fig.
5 (a)) and the proton effective FF (Fig. 5 (b)) from all the analyses with the ISR process at BABAR and BESIII experiments, together with other available experimental data from direct annihilation process.

3.3. The ratio of the proton FFs from the ISR process

Taking advantage of the strong boost of the ISR photon, a full angular distribution of the proton can be obtained from the $e^+e^- \rightarrow p\bar{p}\gamma$ process. This is in contrast to most analyses using the direct annihilation process, which have to limit the angular range due to detector acceptance. Therefore, the ISR method allows to extract the ratio of the proton FFs with a relative higher precision comparing to direct annihilation measurements with comparable statistics. Both LA-ISR analyses from BABAR and BESIII measured the ratio of the proton FFs at the $p\bar{p}$ invariant mass region of threshold - 3.0 GeV/$c^2$ for six mass intervals, while the BESIII SA-ISR analysis measured the ratio between 2.0 - 3.0 GeV/$c^2$ for three mass intervals with reduced proton angular distributions. Figure 6 shows examples of proton angular distributions including a fit to extract the ratio of the proton FFs [12,16,17].

The results of the extracted ratio of the proton FFs from the three measurements are shown in Fig. 7, including measurements from direct annihilation processes. Compared to the Born cross section measurements, the uncertainty both in terms of $R_{em}$ (y axis) and $\sqrt{q^2}$ (x axis) is till very large due to limited statistics. The results of the proton FFs ratio are consistent for measurements (direct annihilation and ISR processes) from the $e^+e^-$ collider experiments. At the region close to the $p\bar{p}$ threshold ($q^2 < 4.2 \text{ (GeV/c)}^2$), recent results of the ratio obtained with ISR process at BABAR and BESIII, as well as by the most precise measurement with the direct annihilation process at BESIII, disfavor of the early measurement from the PS170 experiment with $p\bar{p} \rightarrow e^+e^-$ annihilation process.

Figure 6. Examples of proton angular distributions including a fit to extract the ratio of the proton FFs from the BABAR (a) and BESIII (b) LA-ISA analyses (threshold-1.95 GeV/$c^2$), and the BESIII SA-ISR (c) analysis (2.3-2.6 GeV/$c^2$) [12,16,17].
Figure 7. The ratio of the proton FFs from BABAR and BESIII LA-ISR analyses at the $p\bar{p}$ invariant mass region of threshold-3.0 GeV/c$^2$, and from BESIII SA-ISR analysis at the mass region of 2.0-3.0 GeV/c$^2$. Results also include measurements from PS170, BESIII (direct annihilation) and CMD-3 experiments [47–49]. The dotted line is the fit result in Ref. [46], the dot-dashed line shows a new fit result with the same formula by including both BESIII ISR results, and the grey band shows the standard deviation of this fit.

4. Discussions and conclusions

4.1. Phenomenology studies on the proton EMFFs

The QCD calculation of the nucleon EMFFs in the few GeV momentum transfer region, where non-perturbative methods are required, is complicated. Different models have been developed to describe the data in the space-like region but only some of them can be extended to the time-like region (for review see Refs. [37,38]), such as the models based on dispersion relations [39] and vector meson dominance [40,41]. This region has recently attracted a lot of attention, in particular after the precise ISR measurements from BABAR were available. The BABAR data on the $e^+e^-\rightarrow p\bar{p}$ Born cross section and on the effective EMFF show evidence of some structures (Fig. 5). These structures have been later confirmed by the 3 independent analyses from the BESIII collaboration based on ISR and energy scan techniques. Theoretical studies have attempted to reproduce these structures and to provide an explanation of their origin. In 2014, an improved parametrization of the nucleon EMFFs based on generalized vector dominance has been developed and implemented in the PHOKHARA event generator [36]. It describes well the measurements from BABAR, as well as the space-like data on the proton form factor ratio using polarized beam and/or target. In 2015, Lorenz et al. analyzed the EMFFs ratio and the effective FF of the proton from both TL and SL regions, and discussed possible contributions to the nucleon FFs from the vector meson $\phi(2170)$ or from final-state interaction (FSI) at the $N\bar{N} + c.c$ and $\Delta\bar{\Delta}$ thresholds [42]. A recent phenomenology study, by Cao and Dai, has a joint discussion on the effective FF of proton and neutron, where the periodic structures could be explained by the contributions from pure isoscalar or isovector, or their orthogonal interference [43].
Figure 8. Periodic oscillation structure of the proton effective FF. The dotted line represents the oscillation contribution, which is described by Eq. 12 and the value of fit parameters are taken from Ref. [45].

In 2015, Bianconi and Tomasi-Gustafsson studied the proton effective FF from BABAR LA-ISR measurement, and found the data can be best reproduced by a three-pole function (\(F_3(p(s))\)) with an additional periodic oscillation part (\(F_{osc}(p(s))\)) [44,45]. By including more experimental data from BESIII (direct annihilation and SA-ISR analyses) and CMD-3 experiments, this research was updated in 2021 [46].

Similar to the effective FF of the proton, a fit was performed in Ref. [46] on the ratio of the proton EMFFs with the function including a monopole decrease and a damped oscillation,

\[
\frac{R_{em}(q^2)}{R_{em}(q^2)} = 1 + \frac{1}{1 + (q^2 - 2m_p)^2 / r_0^2} \left[ 1 + r_1 e^{-r_2(q^2 - 2m_p)} \sin(r_3(q^2 - 2m_p)) \right].
\]

As shown in Fig. 7, the fit (dotted line), performed in Ref. [46], was only applied on the results from BABAR LA-ISA and BESIII energy scan (2020) measurements. By including more experimental results from both BESIII ISR measurements, a new fit (dot-dashed line in Fig. 7) is performed in this report, in which the result is slightly changed with an improved fitting quality. The grey shadow represents a one standard deviation band.

4.2. Discussion of the proton EMFFs from the ISR process

The ISR Process has advantages to investigate the proton EMFFs at the \(e^+e^-\) collider experiments.

So far, it is the only method used to extract the ratio of proton EMFFs at the pp threshold. Because of the very low momentum of the produced proton/anti-proton at the threshold from the direct annihilation process, it is not possible to reconstruct the
charged tracks in a tracking system of the detector. The CMD-3 experiment has measured the cross section of \( e^+ e^- \rightarrow p \bar{p} \) at the invariant mass very close to the threshold (1.89 and 1.90 GeV/\( c^2 \)) by counting the annihilation of the antiproton in the beam pipe or in the drift chamber (tracking sub-detector) \[49\]. The ratio or the individual FF could not be extracted at these invariant mass regions because the angular distribution analysis is impossible without the proton/antiproton charged track reconstruction. With the strong boost of an ISR photon, the proton and antiproton are produced at their threshold with large momenta, therefore full information of the momentum and PID can be obtained for the charged tracks of the \( p \bar{p} \) system, thus it is possible to extract the ratio of the proton EMFFs (or individual FFs) by analyzing the angular distribution of the proton at the \( p \bar{p} \) threshold region.

Table 2: A simple comparison for the precision of the proton FFs ratio measured by the ISR process and the direct annihilation process from BABAR, BESIII and CMD-3 experiments. [Note: the uncertainty of the proton FFs ratio \((\Delta R_{\text{em}}/R_{\text{em}})\) is statistical only, except the one from BESIII SA-ISR analysis.]

| \( q \) [GeV/\( c \)] | \( N_{\text{evt}} \) | \( 1/\sqrt{N_{\text{evt}}} \) | \( \Delta R_{\text{em}}/R_{\text{em}} \) | experiment |
|----------------|----------------|-----------------|----------------|-------------|
| 2.025 - 2.100 | 1328           | 2.74\%          | 10.79\%         | BABAR LA-ISR [12] |
| 2.025 - 2.100 | 560            | 4.23\%          | 18.49\%         | BESIII LA-ISR [17] |
| 2.0 - 2.3     | 4283           | 1.53\%          | \( \sim 23.39\% \) | BESIII SA-ISR [16] |
| 2.125         | 50312          | 0.45\%          | 3.39\%          | BESIII energy scan [48] |
| 1.92 - 2.00   | 2577           | 1.97\%          | 15.44\%         | CMD-3 (combined) [49] |

A full angular distribution of the proton improves the precision of the ratio of the proton FFs. It is not possible to have a full angular distribution of the proton from the direct annihilation process due the non-\(4\pi\) acceptance of a detector. As another benefit of the boost of the ISR photon, a full angular distribution of the proton (Fig. 6) is obtained in the \( p \bar{p} \) c.m. frame, and the ratio is extracted with higher precision by fitting to the full angular distribution. Table 2 lists a simple comparison for the precision of the proton FFs ratio, which were measured by the LA-ISR analyses from BABAR and BESIII, the SA-ISR analysis from BESIII, and the direct annihilation analyses from BESIII and CMD-3 experiments. The impact of the full angular distribution can be seen by comparing the statistical uncertainty on the proton FFs ratio to the corresponding one of the total number of observed events.

In addition, the ISR method provides continuous measurements of the proton EMFFs in a large \( p \bar{p} \) invariant mass range. The combined BABAR and BESIII ISR measurements of the Born cross section and the proton effective FF cover the range from the threshold up to 6.5 GeV/\( c^2 \), while the existing data from scan experiments are only available at discrete \( p \bar{p} \) invariant mass points below \( \sim 4.2 \) GeV/\( c^2 \).

4.3. Expectation of the nucleon EMFFs measurements through ISR technique

The disadvantage of the ISR process for the proton EMFFs measurement is obviously that the statistics is much lower compared to the direct annihilation process, therefore very high luminosity is necessary to compensate. The Belle-II experiment on the B-factory SuperKEKB is starting data collection and will be able to contribute for the proton EMFFs study in the future. The Belle-II experiment has the goal to obtain a total integrated luminosity of 50 ab\(^{-1}\) in the c.m. energy range from 9.46 to 11.24 GeV, and it has planned to collect \( \sim 5 \) ab\(^{-1}\) integrated luminosity in 2020 \[50\]. According to a recent report, the plan is delayed and an integrated luminosity of 231 fb\(^{-1}\) was accumulated until 2021 \[51\]. The BESIII experiment is continuing to collect data between 2.00 - 4.95 GeV, where many large data sets might be helpful to improve measurements of the proton EMFFs in a large \( q^2 \) range, and it is even possible to access other baryon-antibaryon channels. The BESIII experiment has accumulated large luminosity data sets above 3.770 GeV. The data sets, which can be used for the baryon EMFFs measurements...
with ISR technique, are estimated to be \( \sim 22 \text{ fb}^{-1} \) until to 2021 [52]. In next two years, BESIII will collect data at \( \sqrt{s} = 3.773 \text{ GeV} \) to obtain a total luminosity up to \( 20 \text{ fb}^{-1} \) (including the 2.9 fb\(^{-1} \) from previous data) [53,54]. Considering that one disadvantage of the ISR technique is worse resolution of the \( p\bar{p} \) invariant mass, BESIII experiment also plans to explore the nucleon production threshold region through direct annihilation process by taking data below 2.0 GeV [55].

Regarding the expected luminosities from both experiments in the next few years, researches for the EMFFs of the proton may achieve significant progress with the ISR technique, especially for the EMFFs ratio of the proton close to the \( p\bar{p} \) threshold region, where the detection efficiency is almost zero for the low momentum proton/antiproton tracks produced from the direct annihilation process.

### 4.4. Summary

The ISR technique to analyze proton EMFFs is not only a complementary method, but also has the advantages to access the proton-antiproton threshold and to improve the precision of the ratio measurement with full proton angular distribution analysis. The BABAR experiment started the proton EMFFs research with the ISR technique, and the results of the proton EMFFs ratio show a tension on the ratio of the proton EMFFs to the results from previous experiment PS170. BESIII experiment performed the proton EMFFs measurements through the direct annihilation and ISR processes with different data sets, very high precision for the measurements on the \( e^+e^- \rightarrow p\bar{p} \) cross section and the FFs (ratio) is achieved from the direct annihilation analysis, and large invariant mass range from the \( p\bar{p} \)-threshold to 3.8 GeV/c\(^2 \) is covered from the ISR analyses. Future measurements with higher precision, in particular close to the \( p\bar{p} \) threshold, will enhance our knowledge on the proton EMFFs in the time-like region.
