V2O5-Based nanomaterials: synthesis and their applications

Xuyan Liu, a Jiahuan Zeng, a Huinan Yang, b Kai Zhou a and Deng Pan a

As an important part of lithium-ion batteries, the cathode material can directly affect the performance of lithium-ion batteries. However, with the increasing demand for high-energy and high-power devices, the energy and power density of electrode materials need to be further improved. Among all metal oxides, vanadium pentoxide (V2O5) is regarded as a promising candidate to serve as a cathode material for LIBs due to its high theoretical capacity. Herein, a thorough survey of the synthesis of V2O5-based nanomaterials with various structures and chemical compositions and their application as positive electrodes for LIBs is provided. This review covers V2O5 with different morphologies ranging from 1D nanorods/nanowires/nanotubes/nanofibers/nanobelts, to 2D nanosheets, and to 3D hollow and porous nanostructures. Nanocomposites consisting of V2O5 and different carbonaceous supports, e.g., amorphous carbon, carbon nanotubes, and graphene, are also investigated. The cation-doped V2O5 samples as the cathode material for LIBs are briefly discussed as well. The aim of this review is to provide an in-depth and rational understanding of how the electrochemical properties of V2O5-based cathodes can be effectively enhanced by achieving proper nanostructures with optimized chemical composition.

1. Introduction

Recently, with the shortage of traditional energy sources and fear of greenhouse gas-induced global warming, scientists and engineers are looking for renewable, highly efficient methods of creating and storing energy without disruption to the environment.1-2 With the increasing demand for green energies in the 21st century, efforts have been devoted to replace the non-renewable fossil fuels by other sustainable energies, like solar, wind, nuclear and hydroelectric power.3 Therefore, long-life, environmentally friendly, and low-cost reliable batteries are greatly needed to meet the crucial energy storage demands of modern society. Since lithium-ion batteries were first commercialized in 1991 by Sony, they have been widely used in many fields such as consumer electronics because of their high energy density and high safety.4,5 Nowadays, lithium-ion batteries (LIBs) and supercapacitors (SCs) represent two major practically applied energy storage systems; nevertheless, both have some shortcomings originating from their charge storage mechanisms.6 In this regard, rechargeable LIBs play a significant role due to their high gravimetric and volumetric energy, high power density, long cycle life and low self-discharge property.7-9 Furthermore, they have proved to be the most efficient energy storage strategy for a wide range of portable devices like cellular phones, laptops and digital electronics.10-12 Current LIB technology is well developed for portable electronic devices and has been widely used for the past twenty years. However, the employment of Li-ion batteries in hybrid electric vehicles (HEV), plug-in hybrid electric vehicles (PHEV) and pure electric vehicles (PEV) needs two to five times more energy density than the existing lithium batteries can offer (150 Wh kg-1).13 Therefore, further LIB material and system developments are necessary.

Fig. 1 shows a typical lithium-ion battery.25 Obviously, there are four key components in an LIB system: cathode, anode, separator and electrolyte.14 The electrolyte allows lithium ions to travel between the electrodes, and a separator keeps the...
Review

anode and the cathode from making direct contact. First-generation LIBs employ the graphite as the anode, layered LiCoO2 as the cathode, and the organic liquid LiPF6/ethylene carbonate (EC)/dimethylene carbonate (DMC) as the electrolyte. The LIB performance (e.g., cell potential, capacity and energy density) is largely dependent on the intrinsic chemistry of the negative and positive electrode materials. The cathode usually consists of a metal oxide, and the anode tends to be a carbon material. At present, cathode materials for commercial LIBs are mainly transition metals oxides or active phosphates, such as LiCoO2, LiNiO2, LiMn2O4, and LiFePO4. Comparison of several kinds of cathode materials for lithium ion batteries is listed in Table 1, while graphite is commonly used as the anode active material. Lithium-ion batteries charge and discharge through a process of lithiation (lithium insertion) and de-lithiation (lithium extraction) by means of electrochemical reactions. In this process, lithium ions diffuse back and forth through the electrolyte between the anode and the cathode. During lithiation (discharging), the lithium bonded with the anode material breaks apart, producing lithium ions and electrons, and these lithium ions travel and bond with metal oxides on the cathode side and the electrons produce the electrical energy that powers devices. During de-lithiation (charging), the lithium metal oxides from the cathode break apart, producing lithium ions that pass through the electrolyte and bond with the material on the anode side with the addition of electrons.

In the past decade, because of the significant advances in nanotechnology and materials science, numerous nanostructured materials have been applied as electrode materials for LIBs. Among the potential cathode materials, layered vanadium pentoxide (V2O5) is one of the most attractive cathode materials and has been extensively studied because of its low cost, abundance, ease of synthesis, good safety and relatively high theoretical capacity of ~437 mA h g–1, which is much higher than that of the currently used LiCoO2-based anodes (~274 mA h g–1). In a Li/V2O5 half-cell, the Li+ intercalation and de-intercalation process can be expressed by the following equation:

\[ \text{V}_2\text{O}_5 + x\text{Li}^+ + xe^- \rightarrow \text{Li}_x\text{V}_2\text{O}_5 \]

As Li+ are inserted into the layers of V2O5, phase transformation occurs. Theoretically, the process of Li+ intercalation into V2O5 can be divided into several stages and different phases of LiₓV₂O₅ can be formed in each stage. Fig. 2 shows the electrochemical lithium intercalation into V₂O₅, showing the evolution of phases with the degree of lithium intercalation. The structural behaviour of vanadium oxide with increased Li insertion is quite complex and it can split into several different phases. According to the amount of lithium, x, there are five phases, \( \alpha-V_2O_5 (x = 0.01) \), \( \varepsilon-Li_2V_2O_5 (0.35 < x < 0.7) \), \( \delta-Li_xV_2O_5 (x = 1) \), \( \gamma-Li_xV_2O_5 (x < 2) \) and \( \omega-Li_xV_2O_5 (x > 2) \). The phases of the lithiated vanadium oxide LiₓV₂O₅ and the corresponding electrochemical reactions are listed in Table 2. Among these phases of LiₓV₂O₅, the first phase \( \alpha-V_2O_5 \) has little effect on the V₂O₅ structure. This phase is followed by the \( \varepsilon \)-phase in which the vanadium oxide layers become more puckered. The \( \delta \)-phase occurs when \( x = 1 \), and as can be seen from Fig. 2, at this phase, there is a sudden decrease in cell potential. Due to the intercalation of Li+, slight structural modifications occur, such as puckering of the layers and increasing of interlayer spacing; however, the basic layered structure is maintained. If more than one Li+ are intercalated, the \( \delta \)-phase is transformed into the \( \gamma \)-LiₓV₂O₅ phase via an irreversible reconstruction mechanism. The \( \gamma \)-LiₓV₂O₅ phase can itself be reversibly cycled in the range of \( 0 < x < 2 \) while maintaining the \( \gamma \)-type structure. When even more Li+ are intercalated, a rock salt structure of \( \omega-Li_xV_2O_5 \) is irreversibly formed. It has been reported that discharging V₂O₅ to the \( \omega-Li_xV_2O_5 \) phase would result in a rapid capacity loss with increased cycling, which is not desirable for the cathode material. Although the theoretical capacity of V₂O₅ is pretty high, the practical capacity of unmodified V₂O₅ is far from

### Table 1 Comparison of several kinds of cathode materials for lithium-ion batteries

| Material category | LiCoO₂ | LiNiO₂ | LiMn₂O₄ | LiFePO₄ |
|-------------------|--------|--------|---------|---------|
| Operating voltage/V | 2.5–4.2 | 2.5–4.2 | 3–4 | About 3.4 |
| Theoretical capacity/mA h g⁻¹ | 274 | 275 | 148 | 170 |

Fig. 2 Various phases associated with the electrochemical intercalation of lithium into V₂O₅.
we will provide an overview of the formation of V2O5 materials. The morphologies of V2O5 are prepared by the hydrothermal method, reverse micelle techniques, and electrochemical methods, including sol–gel processing, template-based methods, thermal evaporation, hydrothermal/solvothermal approaches, and electrospinning. These methods have been widely used in photocatalysts, sensors, and electrochromic devices. To synthesize nanostructured V2O5, a variety of methods, including sol–gel processing, template-based methods, thermal evaporation, hydrothermal/solvothermal synthesis, reverse micelle techniques, and electrochemical deposition, have been developed. Among these methods, hydrothermal synthesis is considered the easiest and most effective way. With the assistance of surfactants, different morphologies of V2O5 are prepared by the hydrothermal method.

Table 2 Phases of the lithiated vanadium oxide Li$_x$V$_2$O$_5$ and the corresponding electrochemical reactions

| Value of $x$ in Li$_x$V$_2$O$_5$ | Phase | Electrochemical reactions |
|-----------------------------|-------|--------------------------|
| $x < 0.01$                  | $\alpha$-V$_2$O$_5$ | V$_2$O$_5$ + $x$Li$^+$ + $xe^-$ $\rightarrow$ $\alpha$-Li$_x$V$_2$O$_5$ |
| 0.35 $< x < 0.7$            | $\varepsilon$-Li$_x$V$_2$O$_5$ | V$_2$O$_5$ + $x$Li$^+$ + $xe^-$ $\rightarrow$ $\varepsilon$-Li$_x$V$_2$O$_5$ |
| $x = 1$                     | $\delta$-Li$_x$V$_2$O$_5$ | V$_2$O$_5$ + $x$Li$^+$ + $xe^-$ $\rightarrow$ $\delta$-Li$_x$V$_2$O$_5$ |
| $x < 2$                     | $\gamma$-Li$_x$V$_2$O$_5$ | V$_2$O$_5$ + $x$Li$^+$ + $xe^-$ $\rightarrow$ $\gamma$-Li$_x$V$_2$O$_5$ |
| $x > 2$                     | $\omega$-Li$_x$V$_2$O$_5$ | V$_2$O$_5$ + $x$Li$^+$ + $xe^-$ $\rightarrow$ $\omega$-Li$_x$V$_2$O$_5$ |

satisfactory because of low electrical conduction, slow Li$^+$ diffusion and irreversible phase transitions upon deep discharge. This would induce a huge influence in the electrode material, which leads to disintegration and loss of electric contact and eventually results in quick capacity fading upon prolonged cycling.

In this review, we propose a systematic description of V2O5-based nanomaterials ranging from synthesis, to modification, structure and electrochemical application. In the first section, we will provide an overview of the formation of V2O5 materials through dimensional structure design. It includes the survey of phase-pure V2O5 with unique 1D, 2D, and 3D nanostructures. Then, we will illustrate the development of carbonaceous materials into V2O5 electrodes for LIBs. In the last section, cation-doped V2O5 samples as the cathode material for LIBs will be briefly discussed. We thus believe that this review article could serve as a good reference for V2O5-based nanomaterials.

2. Phase-pure V2O5

As a cathode material for LIBs, vanadium-based oxides have attracted worldwide attention because of their high capacity, low cost and abundance. Moreover, V2O5 has also been widely used in photocatalysts, sensors, and electrochromic devices. To synthesize nanostructured V2O5, a variety of methods, including sol–gel processing, template-based methods, thermal evaporation, hydrothermal/solvothermal synthesis, reverse micelle techniques, and electrochemical deposition, have been developed. Among these methods, hydrothermal synthesis is considered the easiest and most effective way. With the assistance of surfactants, different morphologies of V2O5 are prepared by the hydrothermal method.

2.1 1D nanostructures

Among the many vanadium oxide nanomaterials, one-dimensional nanostructured vanadium oxide is the most studied because its preparation method is relatively simple, it has a large specific surface area compared with traditional cathode materials, and it shows good cycling stability and high specific capacity. Among the various types of nanostructures, 1D V2O5 nanostructures with nanoscale radial dimensions, including nanorods, nanowires, nanotubes, and nanobelts, have exhibited distinct advantages in LIBs.

2.1.1 V2O5 nanorods. In 2008, Glushenkov’s group reported a novel solid-state process capable of producing large quantities of belt-like V2O5 nanorods. In this approach, V2O5 powder was mechanically milled in a ball mill first to produce a nanocrystalline precursor and then annealed in air. Nanorods were formed via a controlled recrystallization process during annealing. The growth process, morphology and structure of the nanorods were presented. The authors discovered that the annealing time was advantageous for the nanorod formation. Starting from the second cycle, the nanorods maintained a stable capacity of around 260 mA h g$^{-1}$ with no sign of significant degradation. The V2O5 nanorods in our study demonstrated a good cycling stability, which could be correlated to their small size and beneficial crystal orientation. Zhu et al. discovered an electrospinning method to produce V2O5 nanorods (Fig. 3). The method added H$_2$C$_2$O$_4$ to increase the solubility of cheap NH$_4$VO$_3$ in water at room temperature and took mixed solvent of deionized water and N,N-dimethylformamide (DMF) to make the spinning process easier. In the end, V2O5 micro/nanorods were successfully prepared. Further, the V2O5 micro/nanorod cathodes showed a high lithium storage performance with the first discharge capacity of 418.8 mA h g$^{-1}$ and the 50th discharge capacity of 180.5 mA h g$^{-1}$ when the half-cell was cycled between 2.0 and 4.0 V at a current density of 50 mA g$^{-1}$.

Subsequently, Glushenkov et al. prepared nanorods of V2O5 via a two-stage procedure of ball milling and annealing in air. Commercially purchased V2O5 powder was milled in a ball mill as the first step of the synthesis. The as-milled precursor was subsequently annealed in air to produce nanorods via solid-state recrystallization. Takahashi et al. synthesized single-crystal V2O5 nanorod arrays using template-based electrodeposition and the electrochemical results demonstrated that the nanorod array electrodes had significantly higher current density and energy storage density than sol–gel-derived V2O5 films. Uniformly sized vanadium oxide nanorods with a length of about 10 μm and with diameters ranging from 100 to 200 nm were grown over a large area with near unidirectional alignment. This electrode exhibited high rate discharge capacity and good cycling stability.

2.1.2 V2O5 nanowires. Since oxide nanorods were first produced by Yang and Lieber in 1996, oxide nanorods and nanowires have received great interest. Recently, oxide nanowire electrodes have been found to exhibit excellent cycling performance because of their high surface area, short Li-ion diffusion distance, and facile strain relaxation on electrochemical cycling. Particularly, among all nanomaterials, nanowires not only reduce the volume strain, but also provide effective channels for the transmission of electrons along the length. Mai et al. prepared ultralong hierarchical vanadium oxide nanowires by electrospinning combined with annealing. They used cheap ammonium metavanadate as the raw material; after the addition of polyvinyl alcohol (PVA) in water and ammonium metavanadate, a precursor aqueous solution was prepared. Then the NH$_4$VO$_3$/PVA composite nanowires were...
prepared by electrospinning, and the surface of the nanowires was bonded with nanorods with a diameter of about 50 nm and length of about 100 nm. The electrospun composite nanowires were then annealed at 480 °C in air for 3 h to obtain vanadium oxide nanowires. After annealing, the nanowires could retain their length as continuous structures, while the diameter

decreased to 100–200 nm. Notably, it was found that the ultra-long vanadium oxide nanowires were constructed from attached nanorods of diameter of approximately 50 nm and length of 100 nm. In the voltage window of 1.75–4.0 V, the cathode obtained an initial discharge capacity of 390 mA h g \(^{-1}\) and 201 mA h g \(^{-1}\) during the first and 50th cycles at a current density of 30 mA g \(^{-1}\), respectively. Moreover, the as-prepared ultralong hierarchical vanadium oxide nanowires were found to offer high charge/discharge capacities and improved cycling stability.

Velazquez et al.\(^66\) prepared V\(_2\)O\(_5\) nanowire arrays on silicon substrates by the thermal evaporation method. The nanowires obtained were single crystalline and highly oriented with their lengths and substrate coverage controlled by the duration of the reaction, reaction temperature, and flow velocity. The growth of these nanowire arrays has great value in the fabrication of novel battery architectures based on individual nanowires. Ramasami et al.\(^68\) synthesised a V\(_2\)O\(_5\) NWC by the combustion method using cassava starch. The noteworthy features of the synthesis are that it is a simple and time-saving process, gives high yield, and uses naturally occurring fuel that doubles up as a template for the growth of nanowires/nanorods. The schematic representation of the nanowire cluster formation is given in Fig. 4. The V\(_2\)O\(_5\) NWC exhibited an initial discharge and charge capacity of 209 and 206 mA h g \(^{-1}\), respectively with a corresponding coulombic efficiency of 96% and the obtained discharge capacity at the 30th cycle was 198 mA h g \(^{-1}\). The discharge capacity fading was found to be negligible (with a small fading rate of 0.1% per cycle) from the beginning to the 50th cycle. The capacity retention in the 30th cycle was 95% with respect to the first cycle capacity. Compared to previous literature,\(^70,71\) the as-prepared structure behaved as a superior material with respect to capacity and cycling stability.

2.1.3 V\(_2\)O\(_5\) nanotubes. Compared with nanowires, the nanotubes have different contact areas, such as the inner and outer walls of the tube. The tubular structure can serve as a channel for filling the electrolyte, which is conducive to the promotion of ion transport. For the preparation of vanadium oxide nanotubes, the hydrothermal method is the most commonly used method. However, the fabrication of vanadium oxide nanotubes by hydrothermal synthesis is a very complicated process. In principle, nanotube arrays have larger surface areas than nanorod arrays. In addition, the tubes can operate as electrolyte-filled channels for faster transport of ions to the intercalation sites. As for the previous literature, template-based electrodeposition is a simple and efficient route for producing oxidic nanorods and nanotubes. Wang and co-workers\(^72\) used this method to prepare well-defined V\(_2\)O\(_5\) nanotubes. Investigation of its electrochemical properties showed that the nanotube array possessed a high Li\(^+\) intercalation capacity of 300 mA h g \(^{-1}\). Although the capacities of the nanotube array decreased during cycling, the array achieved stabilized capacities within 10 cycles. The stabilized capacity of the nanotube was approximately 160 mA h g \(^{-1}\), which was 30% higher than the stabilized capacity of the film. The initial high capacity of the nanotube was obviously ascribed to the large surface area and short diffusion distances provided by the nanostructure. Cui et al.\(^73\) presented a convenient and controllable approach to synthesize lithium vanadium oxide nanotubes by a combined sol–gel reaction and hydrothermal treatment procedure.

Nadimicherla et al.\(^74\) synthesized V\(_2\)O\(_5\) nanotubes and PEG surfactant V\(_2\)O\(_5\) nanotubes by a simple hydrothermal method. Batteries using V\(_2\)O\(_5\) nanotube electrodes showed an initial specific capacity 192 mA h g \(^{-1}\), whereas the PEG surfactant V\(_2\)O\(_5\) nanotubes exhibited a value of 204 mA h g \(^{-1}\). It was found that the PEG surfactant V\(_2\)O\(_5\) nanotubes showed higher specific capacity at the initial stages and better stability as cycling progressed than the V\(_2\)O\(_5\) nanotubes. This was due to the fact that polyethylene glycol occupied space between the vanadium oxide layers and contributed to the increase in Li\(^+\) intercalation. In addition, polyethylene glycol had a relatively strong interaction with the vanadium oxide layer and had a complex interaction with Li\(^+\), thus effectively alleviating the electrostatic effect of the vanadium oxide layer and Li\(^+\), Li et al.\(^75\) chose commercial V\(_2\)O\(_5\) powder and oxalic acid as the raw materials to obtain a low-cost inorganic vanadium oxalate solution as the electrospinning vanadium precursor, and adopted a facile electrospinning approach followed by annealing to fabricate porous V\(_2\)O\(_5\) nanotubes. The schematic of the synthesis of the porous V\(_2\)O\(_5\) nanotubes is shown in Fig. 5. The sample had highly porous and hollow nanostructures of the as-prepared V\(_2\)O\(_5\) and the as-prepared V\(_2\)O\(_5\) had diameters in the range of 300–500 nm with many pores on the surface. In the voltage window of 2.0–4.0 V, the cathode obtained an initial discharge capacity of 275.2 mA h g \(^{-1}\) and 204 mA h g \(^{-1}\) during the first and 50th cycles at a current density of 58.8 mA g \(^{-1}\), respectively. Moreover, the coulombic efficiency maintained a value of >96% throughout the cycling test.

2.1.4 V\(_2\)O\(_5\) nanofibers. Compared with some other methods, electrospinning is a simple, cost-effective method
that enables the synthesis of nanofibers with diameters ranging from tens of nanometers to several micrometers and a large surface area-to-volume ratio. Yu et al.\textsuperscript{77} prepared mesoporous polycrystalline vanadium oxide nanofibers by electrospinning and high-temperature annealing with V$_2$O$_5$, H$_2$O$_2$ and polyvinylpyrrolidone (PVP) as the starting materials. The resulting nanofibers were 350 nm in diameter and consisted of a porous polycrystalline vanadium oxide with a specific surface area of \approx 97 m$^2$ g$^{-1}$. The mesoporous V$_2$O$_5$ nanofibers demonstrated a significantly enhanced Li-ion storage capacity of above 370 mAh g$^{-1}$ and a high charge/discharge rate of up to 800 mAh g$^{-1}$ with little cyclic degradation. Such mesoporous V$_2$O$_5$ nanofibers allowed easy mass and charge transfer with sufficient freedom for volume change accompanying the lithium ion intercalation and de-intercalation. Cheah et al.\textsuperscript{78} fabricated single-phase polycrystalline high aspect ratio porous V$_2$O$_5$ nanofibers by a simple one-step electrospinning process using V$_2$O$_5$ precursor consisting of vanadium vanadyl acetylacetonate and poly(vinylpyrrolidone), followed by sintering at 400 °C for 15 min. Porosity was caused by the slight shrinkage of the fibers due to the thermal decomposition of the PVP polymer. In the voltage window of 1.75–4.0 V, the cathode achieved an initial discharge capacity of 316 mAh g$^{-1}$ and 158 mAh g$^{-1}$ during the first and 50th cycles at 0.1C rate, respectively. In the voltage window of 2.0–4.0 V, the cathode obtained an initial discharge capacity of 310 mAh g$^{-1}$ and 229 mAh g$^{-1}$ during the first and 50th cycles at 0.1C rate, respectively. Compared with in the 1.75–4 V voltage range, the specific capacity was greatly improved, which was due to the formation of nanoparticles connected to the nanofiber morphology.

Recently, Yan’s group\textsuperscript{79} has proposed a modified, facile and effective electrospinning method to synthesize V$_2$O$_5$ nanofibers using commercial vanadium pentoxide as the precursor material, which is illustrated in Fig. 6. Compared with commercial V$_2$O$_5$ at various current densities, it is evident that V$_2$O$_5$ nanofibers exhibited much better rate capability and cyclic stability. For instance, at a current density of 100 mA g$^{-1}$, the commercial V$_2$O$_5$ electrode exhibited continuous capacity fading in the initial four cycles. Interestingly, the specific capacity for V$_2$O$_5$ nanofibers was recovered after the cathode electrode worked at various current densities for 45 cycles; this performance was significantly better than that of the commercial V$_2$O$_5$ electrode. Dewangan \textit{et al.}\textsuperscript{80} proposed a simple mild one-step hydrothermal technique to prepare uniform V$_2$O$_5$ nanofiber bundles (NBS). The method used a vanadium(v) hydroxlamidino complex as the vanadium source in the presence of HNO$_3$. A bundle is made of an indefinite number of homogeneous V$_2$O$_5$ nanofibers with lengths up to several micrometres and widths ranging from 20 to 50 nm. The as-prepared V$_2$O$_5$ NBS displayed a high electrochemical performance in a non-aqueous electrolyte as a cathode material for lithium-ion batteries.

\subsection*{2.1.5 V$_2$O$_5$ nanobelts.}

Using one-dimensional vanadium pentoxide material, nanobelt structures have also been synthesized. Qin’s group\textsuperscript{81} proposed a template-free hydrothermal method to synthesize ultra-thin VO$_2$(B) nanobelt arrays with a thickness of about 10 nm, which could be converted to V$_2$O$_5$ porous nanobelt arrays by calcining in air at 400°C. In the voltage window of 2.5–4.0 V, a specific discharge capacity of 146 mAh h$^{-1}$ at the 50th cycle as achieved, which is very close to the theoretical capacity of V$_2$O$_5$ crystallite electrodes (147 mAh h$^{-1}$). The coulombic efficiency was nearly 100%, suggesting the good reversibility of the Li-ion insertion/deinsertion process. Even at a much higher current density of 1000 mA g$^{-1}$, a specific discharge capacity of 130 mA h g$^{-1}$ and capacity retention of 128 mA h g$^{-1}$ after 100 cycles could be achieved. The capacity fading rate was calculated to be 0.015% per cycle, suggesting superior capacity retention capability. The excellent rate performance and good capacity retention at various discharge rates are attributed to the interesting porous V$_2$O$_5$ nanobelt array structures. The nano-sized belts reduce the distance of Li-ion diffusion and electron transportation. Moreover, the porous structures of the nanobelt arrays facilitate electrolyte penetration and increase the contact area between the active material and the electrolyte. Furthermore, the porous structure might also be of advantage to accommodate the volume variations during Li-ion intercalation and de-intercalation. Niu \textit{et al.}\textsuperscript{82} successfully fabricated hierarchical V$_2$O$_5$ nanobelts by an economical and facile hydrothermal strategy followed by annealing treatment, as illustrated in Fig. 7. The self-template synthesized hierarchical nanobelt assembled by plate-like nanocrystallines had an open structure with tiny haircuts and a large contract area. When the battery was cycled between 2 and 4 V at a current density of 50 mA g$^{-1}$, the initial discharge capacity was 288 mA h g$^{-1}$. The discharge capacity was 246 mA h g$^{-1}$ at the end of the 50th cycle, with a capacity retention of 85.4%. The good performance of the hierarchical nanobelts can be attributed to their advantages of a hierarchical structure, which is open with tiny haircuts, providing more
pathways for the immersion of liquid electrolyte. Also, these nanobelts have a large and effective surface area, facilitating the electrochemical reaction between the active material and the electrolyte and enable easy strain relaxation to accommodate volume variations during lithiation/delithiation, thus enhancing the structural stability and cyclability.

Wang and co-workers\textsuperscript{83} fabricated a self-standing V\textsubscript{2}O\textsubscript{5} nanobelt electrode free of conductive agents, binders and current collectors by a simple one-step hydrothermal reaction. The length of the V\textsubscript{2}O\textsubscript{5} nanobelts was up to several hundreds of micrometers and the thickness was around 40 nm. The as-prepared sample demonstrated better cycling performance than commercial conventional V\textsubscript{2}O\textsubscript{5} electrodes with a high reversible capacity of 114.4 mA h g\textsuperscript{-1} after 200 charge–discharge cycles. The superior cycling performance of the nanobelt network electrode can be attributed to the excellent structural stability provided by the crosslinked nanobelt network. Rui’s group\textsuperscript{84} demonstrated a cost-effective and green process for the large-scale synthesis of single-crystalline V\textsubscript{2}O\textsubscript{5} nanobelts (in kilogram scale) under ambient conditions by simply vigorous stirring the commercially available V\textsubscript{2}O\textsubscript{5} powder in an aqueous NaCl solution. The as-prepared sample exhibited a higher reversible specific capacity of 242 mA h g\textsuperscript{-1} up to the 50th cycle with a capacity retention at 86%.

For one-dimensional nanostructured materials, the preparation methods are mostly the sol–gel method and hydrothermal method, because these processes are simple and feasible and the requirements of the experimental conditions are not too high. Common nanofibers, nanowires, nanotubes, etc. to some extent have improved the performance of vanadium oxide as a cathode material, such as shortening the diffusion distance of lithium ions and electrons, improving the charge and discharge properties of the electrode material, or increasing the effective contact area to improve the storage of lithium ions and to improve the specific capacity of the material. The superior electrochemical performance of one-dimensional nanostructures can be attributed to the following aspects.

First, one-dimensional nanostructures of V\textsubscript{2}O\textsubscript{5} provide an effective electron transport pathway along the one-dimensional direction. Second, the one-dimensional nanostructures of V\textsubscript{2}O\textsubscript{5} nanotubes with large electrode/electrolyte contact area and hierarchical porous channels provide short Li\textsuperscript{+} diffusion distances. Finally, the existence of pyrolyzed carbon improves the conductivity of the one-dimensional nanostructures. These nanomaterials have a high specific surface area when they are prepared alone. However, when the electrode is prepared, the one-dimensional nanostructures are greatly reduced due to the large surface energy and low mechanical stability, likely resulting in agglomeration and a significant decrease in the specific surface area. Their initial discharge specific capacity will be higher in the charge and discharge tests, but they will produce significant capacity attenuation; also, the number of cycles will not be high in the long cycle performance without further improvement.

### 2.2 2D nanostructures

Two-dimensional nanostructures increase the effective contact area between the electrolyte and the active material, increase the storage capacity of the lithium ions, and shorten the diffusion distance of the lithium ions to meet the demand for high charge and discharge and thus form an ideal structure for the rapid storage of lithium ions. However, the mechanical stress produced by the nanosheets in the process of circulation is easy to make the nanosheets overlap and thicken, weakening the effective contact area of the nanosheets. Therefore, the dispersibility of two-dimensional nanosheets is restricted as an excellent key factor for electrode material performance. It is helpful to effectively improve the electrochemical performance of two-dimensional vanadium pentoxide nanosheets electrode materials by introducing a conductive agent between the nanosheet and increasing the spacing of the nanosheets. Huang\textsuperscript{85} et al. developed an additive-free ultrasonic method with subsequent thermal decomposition to synthesize V\textsubscript{2}O\textsubscript{5} self-assembled nanosheets. The loose V\textsubscript{2}O\textsubscript{5} nanosheets were stacked as 4–6 layers and each layer (∼50 nm in thickness) was assembled using abundant nanoparticles. The as-prepared sample delivered a reversible capacity of 185.6 mA h g\textsuperscript{-1} and 179.5 mA h g\textsuperscript{-1} at the 1st and 50th cycles, respectively, corresponding to a capacity retention of 96.7%. However, NPs V\textsubscript{2}O\textsubscript{5} only had a reversible capacity of 121.4 mA h g\textsuperscript{-1}. After 50 cycles, 87.4% of the capacity (∼106.1 mA h g\textsuperscript{-1}) was retained. All the results demonstrated that the unique structure of SANS V\textsubscript{2}O\textsubscript{5} resulted in improved rate performance and high cycling stability at higher current densities, which was expected to satisfy the requirement of a long cycle life for LIBs.

Rui’s group\textsuperscript{86} proposed a liquid phase separation method to prepare ultrathin V\textsubscript{2}O\textsubscript{5} nanosheets. In the range of 2.05–4 V, the first reversible specific discharge capacity of was 290 mA h g\textsuperscript{-1} at 0.2C. When the rate increased to 50C, the capacity was 117 mA h g\textsuperscript{-1}. This is mainly due to the deposition of lithium ions on the surface of these ultra-thin nanosheets; ultra-thin nanosheets shorten the embedded path of lithium ions to meet the requirements of rapid charge and discharge. An\textsuperscript{87} et al. successfully prepared ultrathin V\textsubscript{2}O\textsubscript{5} nanosheets through a supercritical solvothermal reaction followed by annealing, as illustrated in Fig. 8. As a cathode material for lithium batteries, the ultrathin V\textsubscript{2}O\textsubscript{5} nanosheets exhibited a capacity of 108 mA h g\textsuperscript{-1} at a high rate of up to 10C at 2.4–4 V and excellent
cyclicity with little capacity loss after 200 cycles. The enhanced rate performance is attributed to the shortened diffusion distance and the increased electrode–electrolyte contact area of the ultrathin nanosheet structure. Subsequently, Liang's group prepared a one-step polymer-assisted chemical solution method to synthesize two-dimensional V2O5 sheet networks. This unique method effectively maintains the high specific capacity, rate capability, and cyclability.

As the cathode material of the two-dimensional nanosheet, lamellar nanostructures have a large specific surface area and good structural flexibility, which provide a larger space for the diffusion of ions and can adapt to the volume changes in the cathode material during the lithiation and de-lithiation of lithium, thus improving the cycling stability of the cathode material. If a conductive active material such as carbon nanotubes and carbon black is compounded in the structural material of the nanosheets, it is possible to prevent not only the agglomeration of the nanosheets but also the high conductivity of the active material. At the same time, this reduces the impedance of ions on nanosheets and makes the lithium ions diffuse faster in the electrode material, thus obtaining excellent charge and discharge performance, which is helpful to improve the electrochemical performance of the two-dimensional nanosheet cathode materials. Compared with one-dimensional nanostructured materials, the initial discharge specific capacity of the nanosheets is significantly lower. The reason may be that the vanadium oxide nanosheets are agglomerated in the charging and discharging process, resulting in a significant reduction in the effective contact area, which cannot effectively maintain the high specific surface area of the nanosheets. As with the one-dimensional vanadium pentoxide nanostructures, the long-term cycling performance of nanosheet cathode materials reported in the relevant literature has not improved.

2.3 3D nanostructures

In recent years, three-dimensional structures have attracted considerable attention as an important role of electrode materials. Compared with low-dimensional nanomaterials, three-dimensional nanostructured materials with desired morphologies have been prepared for their superior electrochemical properties as they not only inherit the advantages of low-dimensional nanomaterials, but also maintain the structural stability of the electrode during the Li⁺ intercalation and de-intercalation process. In addition, the three-dimensional nanostructures are self-supporting, and the nanocomposites are not prone to agglomeration during circulation. Also, the...
pore structure of the prepared electrode material is maintained for a long time. Thus, under the same electrochemical cycling test, vanadium pentoxide electrode materials have a three-dimensional or graded structure exhibiting better electrochemical performance than the low-dimensional electrode materials and better cycling stability. Compared with one-dimensional nanowires, nanotubes and two-dimensional nanosheets, the three-dimensional structure of vanadium oxide shows a variety of peculiar morphologies, such as loose nanoscale structures, and antennae nanospheres, similar to the structure of sea urchins; these strange nanostructures can generally be prepared by adding a templating agent, such as dodecyamine and dodecyl mercapatan. For the three-dimensional nanomaterials of vanadium pentoxide, the most commonly used preparation method is the solvothermal method.

2.3.1 Hollow porous nanostructures. A few years ago, Mai et al. used carbon microspheres as the template to synthesize 3D hollow porous V2O5 quasi-microspheres by a facile solvothermal and annealing method. By selecting an appropriate voltage window, the as-prepared sample exhibited good cycling performance of 283 mA h g\(^{-1}\) at a current density of 100 mA g\(^{-1}\). The excellent electrochemical performance is attributed to the nanosized building blocks of the 3D V2O5 hollow porous structure, which provides a short Li-ion diffusion distance, effective strain relaxation, and large active contact area. By using P123 surfactant as the soft template, Zhang’s group successfully obtained three-dimensional V2O5 hollow spheres by a simple synthesis strategy combining the solvothermal treatment and subsequent thermal annealing. As shown in Fig. 10a, the V2O5 precursor was composed of threedimensional microspheres with diameters in the range of two to three microns. The reversible capacity was 189 mA h g\(^{-1}\) at the end of 50 charge–discharge cycles. It also exhibited satisfactory lithium-ion storage performance. In another similar system, Uchaker and co-workers synthesized nanostructured V2O5 hollow microspheres via a solvothermal route followed by thermal treatment. Previously, Cao et al. prepared self-assembled V2O5 nanorods into microspheres by a mediated polyol process. The method represents a substantial simplification over more conventional methods such as electrostatic spray deposition or thermal evaporation. The as-prepared sample also exhibited good electrochemical performance when they were used as the cathode material in lithium-ion batteries.

Chen and co-workers developed a facile polystyrene sphere template-assisted electrodeposition method for the fabrication of porous multilayer V2O5 hollow sphere arrays on graphite paper substrates. We could clearly see that a 3D porous hollow sphere structure was well formed and the individual hollow sphere exhibited a size of \(~500\) nm (Fig. 10b). We also can reach the conclusion that it is reasonable for the obtained porous multilayer V2O5 hollow sphere arrays to possess impressive porous systems, as these systems will be beneficial for fast ion/electron transfer, leading to fast reaction kinetics. This is especially important for high-rate LIB applications. Wu et al. reported the controllable synthesis of novel rattles-type V2O5 hollow microspheres with the assistance of carbon colloidal spheres as hard templates. Carbon spheres@vanadium precursor (CS@V) core–shell composite microspheres were first prepared through a one-step solvothermal method. V2O5 hollow microspheres with various shell architectures could be obtained after removing the carbon microspheres by calcination in air. When evaluated as a cathode material for LIBs, the rattle-type V2O5 hollow microspheres exhibited superior cycling stability and rate capability. Pan and co-workers proposed a one-pot template-free solvothermal method for the controllable synthesis of uniform VO2 microspheres with different complex interiors, including yolk–shell and multi-shell structures. The VO2 hollow spheres could be readily transformed into V2O5 hollow spheres without any structural deformation by calcination in air. The resulting V2O5 hollow microspheres exhibited a high initial reversible capacity of 256 mA h g\(^{-1}\) at a current density of 300 mA g\(^{-1}\) and good cycling performance over 50 cycles. Pan et al. also reported the synthesis of hierarchical nanosheet-constructed hollow V-glycolate microspheres by a template-free method using a cost-effective VOCl\(_2\) solution as the precursor. After calcination in air, V2O5 hollow hierarchical microspheres with well-preserved structures could be obtained and they were found to exhibit superior rate capability and cycling stability as cathode materials for LIBs.

2.3.2 Hierarchical and porous nanostructures. Wang and co-workers developed a reflux approach followed by annealing to synthesise hierarchical and porous V2O5 microspheres. As is shown in Fig. 10c, the V2O5 microsphere had rough and textured surfaces with porous structures. The superior Li\(^+\) storage performance of the hierarchical and porous V2O5 microspheres could be mainly ascribed to the improved electrode/electrolyte interface, reduced Li\(^+\) diffusion paths, and relieved volume variation during lithiation and delithiation.
processes. An et al. reported the synthesis of porous V2O5 hierarchical octahedrons via a solid-state conversion process. The surface of the octahedrons was smooth, with a diameter range of 3–6 μm [Fig. 10d]. Zhang et al. synthesized novel 3D porous V2O5 hierarchical microspheres by a solvothermal method and subsequent calcination (Fig. 11). These 3D microspheres were constructed by nanoporous fibers, which endowed the electrode with shorter diffusion paths and higher conductivities. When evaluated as a cathode material for lithium-ion batteries, the V2O5 microspheres displayed relatively stable capacity retention at different current rates. They also showed excellent rate capability, with a capacity of 105 mA h g⁻¹ at a 30C rate. The excellent electrochemical performance suggests that these unique hierarchical V2O5 microspheres can be a promising cathode material for lithium-ion batteries.

Recently, Dong et al. developed a facile two-step strategy to synthesize V2O5 microspheres with a hierarchical structure. First, they synthesized a vanadium glycolate precursor by a facile template-free and polyol-mediated solvothermal method and then, they obtained V2O5 microspheres by thermal annealing. Bai and co-workers facilely fabricated hierarchical 3D microspheres consisting of 2D V2O5 (vanadium pentoxide) nanosheets by a low-temperature hydrothermal method. The novel hierarchical micro-/nano-V2O5 electrode exhibited excellent electrochemical performance in terms of high-energy and high-power applications owing to its unique structural properties. These hierarchical 3D micro-/nano-V2O5 possess many unique features advantageous for LIBs: (1) 2D V2O5 nanosheets facilitate Li⁺ diffusion and electron transport; (2) hierarchical 3D micro-/nano-cathode structures built up by V2O5 nanosheet spheres lead to close and sufficient contact between the electrolyte and activate materials and at the same time create a buffer to accommodate volume changes during discharge/charge process; and (3) micro-scale V2O5 spheres easily induce high cell packing density beneficial for high-power batteries. Pan et al. developed a facile solvothermal method to synthesize hierarchical vanadium oxide with various nano/microstructures by simply varying the concentration of the precursor (VOC₂O₄) solution. The V2O5 prepared by solvothermal method for 2 h showed good lithium storage properties with a high reversible capacity of 219 mA h g⁻¹ after 50 cycles. In a follow-up study based on the above experimental results, Pan synthesized hierarchically hollow microflowers composed of nanosheets via a one-pot solvothermal method. After annealing, the sample delivered a high initial discharge capacity of 277 mA h g⁻¹, and the value slightly increased to 284 mA h g⁻¹ in the second cycle probably due to improved electrolyte penetration. With a voltage window of 2.0–4.0 V, the V2O5 hollow microflowers retained a remarkable reversible capacity of 211 mA h g⁻¹ at the end of the 100th cycle.

Chen et al. successfully synthesized hierarchical V2O5 microflowers by a solvothermal reaction followed by a calcination process at 350 °C. The product consisted of uniform flower-like micro-spheres with an average size of around 2 μm. After annealing, the as-prepared hierarchical V2O5 microflowers showed good lithium storage properties with a high reversible capacity of 128 mA h g⁻¹ after 150 cycles at a current density of 200 mA g⁻¹. It was obvious that these capacities were higher than those of bulk V2O5. Ma et al. developed a facile template-less approach for the synthesis of various V2O5 hierarchical structures by calcining the solvothermally prepared VO₂ with different morphologies and structures, which could be simply tailored by adjusting the solvothermal reaction duration. As the cathode materials for lithium-ion batteries, the electrode delivered reversible capacities of 119.2 and 87.3 mA h g⁻¹ at high current densities of 2400 and 3600 mA g⁻¹, respectively, as well as a capacity retention of 78.31% after 80 cycles at 1200 mA g⁻¹. The excellent electrochemical performance could be attributed to the purity of the phase and the synergistic effect between the yolk–shell structure and hierarchical structure of the sub-microspheres. Thus, the three-dimensional nanostructures are more stable than the low-dimensional structures. Nanocomponents are less prone to agglomeration, and the active specific surface area can be maintained for a long time. As can be seen from Table 4, the three-dimensional structures show better cycling performance over prolonged cycling than the low-dimensional structures.

3. V2O5-Based nanocomposites

In addition to phase-pure V2O5, V2O5-based nanocomposites have also been intensively studied as positive electrodes for LIBs. In this section, composites containing V2O5 and other materials will be discussed. In this part, V2O5 with different carbonaceous supports, including amorphous carbon, carbon nanotubes (CNTs), and graphene (Gr) will be surveyed (Table 4).

3.1 V2O5 with amorphous carbon

Amorphous carbon is an inexpensive, frequently used carbonaceous material that is easy to produce in industrial quantities. In LIB applications, amorphous carbon is used to produce a conductive compact outer layer on the surface of V2O5 NPs, which not only serves as a buffer layer to accommodate the volume expansion during cycling but also contributes to the formation of a stable solid electrolyte interface (SEI) layer. In
past research, the use of a carbon layer as a matrix buffer has exhibited superb properties. The carbon layer can also promote the electronic conductivity of the electrodes. As early as 2013, carbon-coated V$_2$O$_5$ nanoparticles, produced via a facile and scalable method via the route illustrated in Fig. 12, demonstrated a first charge capacity of 268 mA h g$^{-1}$ and a capacity of 220 mA h g$^{-1}$ in the 30th cycle at a current density of 29.4 mA g$^{-1}$. This carbon-coated V$_2$O$_5$ showed improved cycling stability and rate performance compared to nanosized V$_2$O$_5$. This approach can be extended to enhance the electrochemical performances of other alternative cathodes. Shin and coworkers reported a facile and scalable method for the synthesis of carbon-coated V$_2$O$_5$ nanoparticles through a carboxylic acid-assisted sol–gel method and controlled calcination. NH$_4$VO$_3$ was used as the vanadium source. Oxalic acid (C$_2$O$_4$H$_2$)$_2$, tartaric acid (C$_4$H$_6$O$_6$)$_2$, and citric acid (C$_6$H$_8$O$_7$)$_2$ were used as both the carbon sources and chelating/reducing agents for preparing three different carbon-coated V$_2$O$_5$ composites. In the voltage window of 2.1–4.0 V, VCA11 had a discharge capacity of 292 mA h g$^{-1}$ for the first cycle and a specific capacity of 261 mA h g$^{-1}$ in the 30th cycle, with a fading rate of 0.36% per cycle. Cheah et al. developed a plasma-enhanced chemical vapour deposition (PECVD) method to synthesize carbon-coated V$_2$O$_5$ nanofibers. The carbon-coated VNFs exhibited better capacity retention characteristics than bare VNFs irrespective of the initial capacity values during prolonged cycling. Such an enhancement is mainly attributed to the homogeneous carbon coating by PECVD, which improves the electronic conducting profiles of VNF and prevents undesired side-reactions with electrolyte counterparts.

Ihsan et al. have recently developed an ultrasound assisted method followed by sintering to fabricate a V$_2$O$_5$/mesoporous carbon composite. Mesoporous carbon, which has pore size between 2 and 50 nm, facilitates electrolyte diffusion into the bulk of the electrode material and hence provides fast transport channels for the conductive ions. Obviously, amorphous structures of carbon and lattice fringes of V$_2$O$_5$ are observed. After sintering, the as-prepared V$_2$O$_5$/mesoporous carbon showed good lithium storage properties with a high reversible capacity of 163 mA h g$^{-1}$ after 100 cycles. The capacity retention of V$_2$O$_5$/mc was considerably higher than that of V$_2$O$_5$ np. Yu et al. rationally designed and synthesized V$_2$O$_5$/ordered mesoporous carbon (CMK-3) composites via an ultrasonic method. The results showed that the ultrasonic synthesis method was flexible and efficient to highly disperse V$_2$O$_5$ nanoparticles in CMK-3. Zhang’s group reported that carbon-
coated V2O5 nanocrystals could be obtained via a unique capillary-induced filling strategy. The obtained nanocrystals exhibited markedly enhanced rate capability and excellent cyclability when used as the cathode material for Li-ion batteries. Guo et al. demonstrated that the electrochemical performance and stability of V2O5 nanowires could be significantly improved by coating a thin carbon layer as the shell. The V2O5@C nanowires exhibited substantially enhanced capacitive performance compared to that of V2O5 nanowires.

3.2 V2O5 with carbon nanotubes

Carbon nanotubes (CNTs) are allotropes of carbon with a cylindrical nanostructure. They find applications in LIB electrode materials owing to their extraordinary thermal, mechanical, and electrical properties. CNTs can be categorized as single-walled nanotubes (SWCNTs) and multi-walled nanotubes (MWCNTs). SWCNTs have high conductivity (\( \approx 104 \, \text{S cm}^{-1} \)) and provide electronic conduction without blocking electrolyte access to the active material. MWCNTs show high mechanical and chemical stability, and the mesoporous character favors the diffusion of the reacting species. CNTs are generally employed as conducting agents to replace carbon black when used in the electrode of LIBs. Nanocomposites containing V2O5 and CNTs are reported to have better lithium storage properties than bare V2O5 materials. This can be attributed to the flexible nature of the CNTs, which alleviate the internal stress caused during the charge-discharge process. With increased conductivity and surface area, such nanocomposites show enhanced lithium storage capability.

By early 2011, Seng et al. prepared free-standing V2O5/MWCNT films by a hydrothermal technique and filtration of ultra-long nanowires. The MWCNTs not only acted as conductive modifiers, but also contributed to forming an integrated web-like structure. Yu’s group proposed a facile hydrothermal approach to fabricate CNTs covered by interconnected V2O5 nanosheets, as illustrated in Fig. 13. After calcination in air, flake-like nanosheets of V2O5 could be observed, which were highly interconnected and covered the CNT skeleton. The interconnected V2O5 NSs were in intimate contact with the CNTs, which was favorable for the enhancement of conductivity. The as-derived CNTs@V2O5 hybrid structure showed a larger reversible capacity over 100 cycles than the V2O5 mf sample. In the voltage window of 2.0–4.0 V, the CNTs@V2O5 electrode delivered a capacity of 285 and 190 mA h g\(^{-1}\) during the 1st and 100th cycle at the current rate of 1C, respectively. Zhou and co-workers used low-cost V2O5 powders and H2O2 as the raw materials to synthesize vanadium oxide nanosheet–MWCNT composite by a simple sol–gel method and hydrothermal process. It was found that V4+ was the predominant V element of the vanadium oxide nanosheet. The addition of carbon nanotubes improved the conductivity of the nanosheet, exhibiting higher specific capacity and cycling stability than materials without carbon nanotubes. When the batteries were cycled between 1.5 V and 4 V at a constant current density of 50 mA g\(^{-1}\), the maximum discharge capacity of the vanadium oxide nanosheet–MWCNT composite was 238 mA h g\(^{-1}\) and 151 mA h g\(^{-1}\), respectively, after the 50th cycle. The good performance of the vanadium oxide nanosheet–MWCNT composite can be attributed to the sheet-like nanostructure having a large specific surface area and good structural flexibility, which can provide more Li+ ion intercalation sites and accommodate large volume variations.

In contrast to the conventional strategy of coating the exterior and/or filling the interior of CNTs with V2O5, Chen et al. proposed a novel strategy to fabricate MWCNT/V2O5 core/shell nanostructures. They first used chemical vapor deposition (CVD) to grow an MWCNT sponge in a quartz tube at 860 °C, which had very low density and high porosity. Then the sponge was cut into the desired size and placed in a commercial ALD reactor, where 1000 cycles of H2O-based ALD V2O5 was deposited on it. The as-derived MWCNT/V2O5 core/shell nanostructures showed excellent electrochemical performance. Zhou’s group have demonstrated that the hydrothermal reaction, protonated hexadecylamine acted as an intermediate. The unique porous nanomaterial architecture of MWCNT–V2O5 provided a large specific surface area and a good conductive network, which facilitated fast lithium ion diffusion and electron transfer. Additionally, the uniformly dispersed MWCNTs conducting network also behaved as an effective buffer that could limit the strain generated during charge–discharge cycles. The as-prepared sample exhibited an initial specific capacity of 402 mA h g\(^{-1}\), and it could remain 222 mA h g\(^{-1}\) after 50 cycles.

3.3 V2O5 with graphene

The use of graphene can also enhance the cycling rate and electrochemical property of V2O5. As an important 2D carbonaceous material, graphene has quickly become an important focus of material science. It has good flexibility, high surface area, and excellent thermal and chemical stability and electrical conductivity. Compared with other carbon materials like amorphous carbon, graphite, and other carbon nanomaterials, graphene nanosheets (GNs) can provide a higher buffer property for the deformation of active anode materials due to their flexibility reaction path and high volume expansion area; graphene also exhibits a better dispersion in nanotubes and nanoparticles.

Recently, Chen et al. successfully prepared reduced graphene oxide (rGO)-encapsulated V2O5 nanocomposites by co-assembly between negatively charged GO and positively charged oxide nanorods (Fig. 14). The process was driven by the mutual electrostatic interactions of the two species and was...
followed by thermal reduction. The as-synthesized nanocomposites possessed flexible and ultrathin rGO shells that effectively enwrapped the oxide nanorods. After several electrochemical tests, the nanocomposites presented excellent results. In the voltage window of 2.0–4.0 V, the cathode achieved an initial charge and discharge capacity of 287 mA h g⁻¹ and 207 mA h g⁻¹ during the first and 50th cycles at a current density of 100 mA g⁻¹, respectively. Cheng’s group reported a simple solvothermal method to directly self-assemble V₂O₅ nanowires on reduced graphene oxide (rGO). The V₂O₅ nanowires/rGO hierarchical nanocomposites exhibited high reversible capacity and good rate capability compared to the bulk material by taking advantage of the synergetic effect of the two components.

Sun et al. developed a hydrothermal method to fabricate hydrated vanadium pentoxide nanoribbons modified with reduced graphene oxide (rGO). The intertwining network provided efficient electron conduction pathways and short Li⁺ diffusion distances. Su and co-workers proposed a hydrothermal method to synthesize flexible V₂O₅ nanowires and then V₂O₅/graphene composites were prepared via the drying-freezing step. It was found that the V₂O₅ nanowires were uniformly decorated on the surface of the graphene sheets. The unique nanocomposite unexpectedly exhibited an enhanced performance compared to pure V₂O₅ nanowires and V₂O₅/graphene composites. Chen et al. developed a facile solvothermal approach to synthesize the composite of V₂O₅ nanoparticles anchored on graphene. The as-prepared sample showed higher capacity and better cyclic capacity retention compared to bare V₂O₅, delivering a high reversible capacity of 153 mA h g⁻¹ after 100 cycles.

4. V₂O₅-Metal composites

In order to overcome the shortcomings encountered in the application of V₂O₅ and improving its electrochemical performance, in addition to the above-mentioned nanocrystalline composites with different carbonaceous supports, cation doping has been an effective approach to improve lithium ion intercalation in V₂O₅, mainly because the introduction of alien ions into the V₂O₅ lattice may tune the ion occupation and the electronic structure of the host material. Recently, utilization of metal nanoparticles to improve the electrical conductivity has attracted extensive attention. Crystal structure stability is important for the V₂O₅ cathode, which can be stabilized by doping of metallic elements such as Al, Cu, Mn, Sn, Ag, Mo, and Ni. Table 5 summarizes the electrochemical properties of the cation doped V₂O₅ samples.

Table 5: Electrochemical performance of cation-doped V₂O₅ samples for Li-ion battery cathode materials

| Precursor material                  | Doped metal | Initial capacity/mA h g⁻¹ | Current density/mA g⁻¹ | Cycles (N)/capacity (mA h g⁻¹) | References |
|-------------------------------------|-------------|---------------------------|------------------------|-------------------------------|------------|
| Vanadyl acetylacetonate             | Al          | 250                       | 35                     | 50/157.5                      | 150        |

| NH₄VO₃                              | Sn          | 251.1                     | 200                    | 50/212                        | 157        |
| NH₄VO₃                              | Cu          | 196                       | 300                    | 70/186                        | 158        |
| VOSO₄ 3H₂O                           | Mn          | 251                       | 300                    | 50/201                        | 159        |
| V₂O₅ powders                        | Mo          | 203                       | 44.1                   | 50/about 92                   | 160        |
| V₂O₅ powders                        | Ag          | 266.1                     | 250                    | 50/276.4                      | 161        |
| NH₄VO₃                              | Ni          | 262                       | 300                    | 50/238                        | 162        |
| V₂O₅ powders                        | Ag          | 266                       | 58.8                   | 50/226                        | 163        |
| V₂O₅ powders                        | Sn          | 350                       | 500                    | 40/355                        | 164        |

Fig. 14 Schematic of the fabrication of rGO enwrapped V₂O₅ nanorods.
density of 58.8 mA g\(^{-1}\), respectively. We could ascribe the better cycling performance of the Fe\(_0\)\_V\(_2\)O\(_5\)\(_{1.5}\) electrode to the improved stability of its layered structure. Li’s group\(^{57}\) developed a microwave-assisted solvothermal synthesis to obtain a series of Sn-doped V\(_2\)O\(_5\) microspheres. The doping of Sn\(^{4+}\) also induced the formation of oxygen vacancies that would allow more active sites for the intercalation/extraction reactions of Li\(^+\). Therefore, the as-prepared sample showed excellent electrochemical properties. It could be attributed primarily to the lattice expansion upon doping that led to higher lithium diffusion coefficient than that of V\(_2\)O\(_5\) as well as the presence of oxygen-rich vacancies.

Zou and co-workers\(^{58}\) developed a simple chemical reaction combined with ultrasonic mixing to synthesize nanostructured composites of V\(_2\)O\(_5\) spheres decorated by electric Cu NPs. The decorated Cu NPs resulted in good contact with active materials and facilitated transportation of the electron into the inner region of the electrode. As expected, the V\(_2\)O\(_5\)/Cu cathodes could afford an obviously better electrochemical performance compared to pure V\(_2\)O\(_5\), with a high reversible capacity of 186 mA h g\(^{-1}\) after 70 cycles under a current density of 300 mA g\(^{-1}\) and good rate performance. Zheng’s group\(^{52}\) developed a facile template-free nickel-mediated polyol process to prepare a high-performance V\(_2\)O\(_5\) hollow microsphere for LIBs, in which nickel acted not only as the mediator to tailor the interior hollow structures of V\(_2\)O\(_5\) and build a favorable 3D hierarchical nano-micron combined architecture, but also as doping units to tune vanadium valence states and improve lithium storage properties. Similarly, V\(_2\)O\(_5\) doped with Cu\(^{2+}\) demonstrated excellent cycling stability and rate capability owing to its modified electronic conductivity and improved structural stability.\(^{55}\) Li et al.\(^{54}\) developed a sol–gel method to synthesize the homogeneous Sn-doped V\(_2\)O\(_5\) sol. Preliminary three-electrode tests of the Sn-doped V\(_2\)O\(_5\) revealed good cycling performance. It was believed that Sn\(^{4+}\) would occupy the interstitial positions between V\(_2\)O\(_5\) slabs and form SnO\(_2\) octahedra with oxygen, leading to a slightly expanded lattice that facilitated Li\(^+\) intercalation/extraction.

5. Conclusion and outlook

We attempt to provide a comprehensive review about V\(_2\)O\(_5\)-based nanomaterials as cathode materials for lithium-ion batteries. Starting with phase-pure V\(_2\)O\(_5\), we have covered a wide range of nanostructures, from 1D nanorods/nanowires/nanotubes/nanofibers/nanobelts to 2D nanosheets and 3D hollow and porous structures. For each category, we have discussed about the synthesis and lithium storage properties. For the 1D nanostructured materials, the most common synthesis methods are the hydrothermal method and sol–gel method. Hence, their preparation process is simple and feasible, and the requirements of the experimental conditions are not too high. For 2D V\(_2\)O\(_5\) nanosheets, the most common synthesis method is the hydrothermal method. Template-free and template-based methods are the main approaches for the synthesis of V\(_2\)O\(_5\) hollow and porous structures. However, all three categories of V\(_2\)O\(_5\) nanomaterials demonstrate significantly better electrochemical properties than bare V\(_2\)O\(_5\) nanoparticles. These can be attributed to the following aspects. First, the nanostructures promote sufficient contact between the electrolyte and active materials. Hence, the nanostructures facilitate rapid electron transfer and mostly avoid the generation of high contact resistance, like a nanoparticle agglomerated structure, thus ensuring satisfactory capacity retention even at high current densities. Finally, the existence of pyrolysed carbon improves the conductivity of the one-dimensional nanostructures.

Nanocomposites consisting of V\(_2\)O\(_5\) and different carbonaceous supports have also been surveyed. Amorphous carbon, graphene, and carbon nanotubes are widely used as supports for electroactive V\(_2\)O\(_5\). In such systems, V\(_2\)O\(_5\) is usually decorated on graphene and CNTs, while amorphous carbon is hydrothermally coated on pre-synthesized V\(_2\)O\(_5\) nanostructures. As potential cathode materials for LIBs, the V\(_2\)O\(_5\) and different carbonaceous composites exhibit highly reversible capacities and better cycling performance. This excellent electrochemical performance is ascribed to their unique structures, which improve electrolyte infiltration and facilitate Li ion diffusion in the electrode. In addition, cation doping of lithium-ion battery (LIBs) cathode materials is beneficial to both ion diffusion and charge transfer in the electrochemical intercalation processes and hence may improve battery rate capability. As the cathode material for lithium-ion batteries, the cation-doped V\(_2\)O\(_5\) samples exhibit better electrochemical performance compared than undoped ones.

By synthesizing V\(_2\)O\(_5\) nanomaterials of various structures, low electrical conduction, slow Li\(^+\) diffusion and irreversible phase transitions upon deep discharge can be alleviated to a certain extent. The cycling performance can be further improved effectively via creating unique nanocomposites. The significant progress achieved in the past decade re-assures the promising use of V\(_2\)O\(_5\) as the cathode material in high-performance lithium-ion batteries. It is reasonable to confirm that V\(_2\)O\(_5\)-based nanocomposites with good electrochemical properties will find wide use in high-performance electrochemical energy storage devices in the near future. Nonetheless, it will still take a long time before metal oxide-based positive electrodes can be incorporated into commercial lithium-ion batteries. While the fundamental electrochemical processes are well understood for V\(_2\)O\(_5\)-based materials, the breakthrough will likely come from the delicate design and synthesis of nanocomposite electrode materials. Future research needs to deeply understand the structural evolution during cycling, possibly through in situ observation techniques and elaborate analysis of their atomic structure.
