A DIAGNOSTIC CRITERION
FOR APPROXIMATE FACTOR STRUCTURE

Patrick Gagliardini\textsuperscript{a}, Elisa Ossola\textsuperscript{b} and Olivier Scaillet\textsuperscript{c,\*}

First draft: February 2014. This version: April 2019.

Abstract

We build a simple diagnostic criterion for approximate factor structure in large panel datasets. Given observable factors, the criterion checks whether the errors are weakly cross-sectionally correlated or share at least one unobservable common factor (interactive effects). A general version allows to determine the number of omitted common factors also for time-varying structures. The empirical analysis runs on ten thousand US stocks from January 1968 to December 2011. For monthly returns, we select time-invariant specifications with at least four financial factors, and a scaled three-factor specification. For quarterly returns, we cannot select macroeconomic models without the market factor.

\textit{JEL Classification:} C12, C13, C23, C51, C52, C58, G12.

\textit{Keywords:} large panel, approximate factor model, asset pricing, model selection, interactive fixed effects.

1 Introduction

Since its introduction by Cattell (1966), we use the scree plot in multivariate statistical analysis as a visual aid for determining an appropriate number of latent factors or principal components. It is a downward line plot of the eigenvalue against the factor number, ordering the eigenvalues from largest to smallest. We look for an elbow in the scree plot to determine graphically the appropriate number of unobservable (latent) factors. The number of selected factors is taken to be the point at which the remaining eigenvalues are relatively small. The aim of this paper is to provide with a valid cut-off point for such a selection rule where we compute the eigenvalues from the sample covariance matrix of residuals of linear models estimated on a large unbalanced panel. Selecting zero unobservable common factors (interactive effects) in the error terms means weakly cross-sectionally correlated errors. This gives an approximate factor structure (Chamberlain and Rothschild (1983)) in Arbitrage Pricing Theory (Ross (1976)) if the linear model relies on observable factors.

For models with unobservable (latent) factors only, Connor and Korajczyk (1993) are the first to develop a test for the number of factors for large balanced panels of individual stock returns in time-invariant models under covariance stationarity and homoskedasticity. Unobservable factors are estimated by the method of asymptotic principal components developed by Connor and Korajczyk (1986) (see also Stock and Watson (2002)). For heteroskedastic settings, the recent literature on large balanced panels with static factors has extended the toolkit available to researchers. A first strand of that literature focuses on consistent estimation procedures for the number of factors. Bai and Ng (2002) introduce a penalized least-squares strategy to estimate the number of factors, at least one. Ando and Bai (2015) extend that approach when explanatory variables are present in the linear specification (see Bai (2009) for homogeneous regression coefficients). Onatski (2010) looks at the behavior of the adjacent eigenvalues to determine the number of factors when the cross-sectional dimension ($n$) and the time-series dimension ($T$) are comparable. Ahn and Horenstein (2013) opt for the same strategy and cover the possibility of zero factors through specifying a mock eigenvalue whose functional form vanishes too. Caner and Han (2014) propose an estimator with a group bridge penalization to determine the number of unobservable factors. A second strand of that literature develops inference procedures for hypotheses on the number of latent factors. Onatski (2009) deploys a characterization of the largest eigenvalues of a Wishart-distributed covariance matrix with large dimensions in terms...
of the Tracy-Widom Law. To get a Wishart distribution, Onatski (2009) assumes either Gaussian errors or $T$ much larger than $n$. Kapetanios (2010) uses subsampling to estimate the limit distribution of the adjacent eigenvalues.

Our paper expands the first strand of the literature by developing a consistent estimation procedure for the number of latent factors in the error terms in a model with observable factors when the cross-section dimension can be much larger than the time series dimension. Concluding for zero omitted factors means weakly cross-sectionally correlated errors. We require $n = O(T^{1/2})$, $\gamma > 0$, and $T = O(n^\gamma)$, $\gamma \in (0, 1]$, which is equivalent to $C_1 n^{2\gamma} \leq T \leq C_2 n^{\gamma}$ for some positive constants $C_1$, $C_2$, so that $\gamma \leq \gamma$. The case $\gamma < 1$ implies $T/n = o(1)$, namely $n$ is much larger than $T$, and the case $\gamma = \gamma = 1$ implies that $n$ and $T$ are comparable. In our empirical application, we have monthly and quarterly returns for about ten thousand US stocks from January 1968 to December 2011, and this explains why we also investigate the setting $T/n = o(1)$. The asymptotic distribution of the eigenvalues is degenerate under the usual standardisation of the $T \times T$ covariance matrix by $n^{-1}$ when the ratio $T/n$ goes to zero as $T, n \to \infty$. In such a setting, we cannot exploit well-defined limiting characterizations (Marchenko-Pastur distribution, Tracy-Widom distribution) obtained when $T/n$ converges to a strictly positive constant. Without such distributional characterizations, we do not see hope for testing procedures as developed by Onatski (2009). However, a key theoretical result of our paper is that we can still have an asymptotically valid selection procedure for the number of latent factors even in the presence of a degenerate distribution of the eigenvalues of the sample covariance matrix of the errors. We show that this extends to sample covariance matrices of residuals of an estimated linear model with observable factors in unbalanced panels. An extension to residuals instead of true errors is not trivial since we need to cope with a projection matrix in the estimated errors, and there are little results about the analysis of the spectrum of matrix products (as opposed to the many results for matrix sums). The unbalanced nature makes things worse since we also have to take care of the matrix of observability indicators in the product. This further explains why we shy away from putting an additional structure on the errors (Onatski (2010), Ahn and Horenstein (2013)) or estimated errors in unbalanced panels in our assumptions. Most of our assumptions are weaker, and the arguments developed in the proofs of the theorems supporting our extension are new to the literature as further commented below.

In this paper, we build a simple diagnostic criterion for approximate factor structure in large cross-
sectional datasets. The criterion checks whether the error terms in a given model with observable factors are weakly cross-sectionally correlated or share at least one common factor. It only requires computing the largest eigenvalue of the empirical cross-sectional covariance matrix of the residuals of a large unbalanced panel and subtracting a penalization term vanishing to zero for large \( n \) and \( T \). The steps of the diagnostic are easy: 1) compute the largest eigenvalue, 2) subtract a penalty, 3) conclude to validity of the proposed approximate factor structure if the difference is negative, or conclude to at least one omitted factor if the difference is positive. Our main theoretical contribution shows that step 3) yields asymptotically the correct model selection. The mechanics of the selection are easy to grasp. If we have an approximate factor structure, we expect a vanishing largest eigenvalue because of a lack of a common signal in the error terms. So, if we take a penalizing term with a slower rate towards zero, a negative criterion points to weak cross-sectional correlation. On the contrary, the largest eigenvalue remains bounded from below away from zero if we face omitted factors. We have at least one non vanishing eigenvalue because of a common signal due to omitted factors. The positive largest eigenvalue dominates the vanishing penalizing term, and this explains why we conclude against weak cross sectional correlation when the criterion is positive. We also propose a general version of the diagnostic criterion that determines the number of omitted common factors. As shown below, we can rewrite the criterion in terms of differences in penalized criteria in the least-squares approach of Bai and Ng (2002) applied on residuals of an unbalanced panel. We derive all properties for unbalanced panels in the setting of Connor and Korajczyk (1987) to avoid the survivorship bias inherent to studies restricted to balanced subsets of available stock return databases (Brown et al. (1995)). The panel data model is sufficiently general to accommodate both time-invariant and time-varying factor structures. Allowing for time-varying factor loadings presents challenges for finance theory and econometric modelling, but Gagliardini et al. (2016), henceforth GOS, explain how to solve these issues and give empirical evidence of time-varying risk premia. We recast the factor models as generic random coefficient panel models and develop the theory for large cross-section and time-series dimensions with \( n = O(T^{1/γ}) \), \( γ > 0 \), and \( T = O(n^{γ}) \), \( γ \in (0, 1] \). Omitted latent factors are also called interactive fixed effects in the panel literature (Pesaran (2006), Bai (2009), Moon and Weidner (2015)). King et al. (1994) use them to capture the correlation between the unanticipated innovations in observable descriptors of economic performance (e.g. industrial production, inflation, etc.) and stock returns. Gobillon and Magnac (2016) use them to get treatment effect estimates in
regional policy evaluation and characterize the generic bias induced by the popular difference-in-differences procedure. To diagnose the absence of an omitted interactive effects is clearly important when applying the difference-in-differences procedure.

For our empirical contribution, we consider the Center for Research in Security Prices (CRSP) database and take the Compustat database to match firm characteristics. The merged dataset comprises about ten thousands stocks with returns from January 1968 to December 2011. We look at a variety of empirical factors and we build factor models popular in the empirical literature to explain monthly and quarterly equity returns. They differ by the choice of the observable factors. We analyze monthly returns using recent financial specifications such as the five factors of Fama and French (2015), the profitability and investment factors of Hou et al. (2015), the quality minus junk and bet against beta factors of Asness et al. (2019) and Frazzini and Pedersen (2014), as well as other specifications described below. We analyze quarterly returns using macroeconomic specifications including consumption growth (CCAPM), market returns and consumption growth (Epstein and Zin (1989)), the three factors in Yogo (2006), the three factors in Li et al. (2006), and the five factors of Chen et al. (1986). We study time-invariant and time-varying versions of the financial factor models (Shanken (1990), Cochrane (1996), Ferson and Schadt (1996), Ferson and Harvey (1999)). For the latter, we use both macrovariables and firm characteristics as instruments (Avramov and Chordia (2006)). For monthly returns, our diagnostic criterion is met by time-invariant specifications with at least four financial factors, and a scaled three-factor FF time-varying specification. For quarterly returns, we cannot select macroeconomic models without the market factor.

The outline of the paper is as follows. In Section 2, we consider a general framework of conditional linear factor model for asset returns. In Section 3, we present our diagnostic criterion for approximate factor structure in random coefficient panel models. In Section 4, we provide the diagnostic criterion to determine the number of omitted factors. Section 5 explains how to implement the criterion in practice and how to design a simple graphical diagnostic tool related to the well-known scree plot in principal component analysis. Section 6 contains the empirical results. In Appendix 1, we gather the theoretical assumptions. In Appendix 2 in the online supplementary materials, we gather the proofs of the propositions of the core text. We use high-level assumptions on cross-sectional and serial dependence of error terms, and show in Appendix 3 that we meet them under a block cross-sectional dependence structure in a serially i.i.d.
framework. In Appendices 4 and 5, we gather proofs of the technical lemmas and further technical details. We place the link of our approach to the expectation-maximization (EM) algorithm proposed by Stock and Watson (2002) for unbalanced panels in supplementary materials available on our author websites. There, we also include some Monte-Carlo simulation results under a design similar to our empirical application to show the practical relevance of our selection procedure in finite samples, and compare them with several alternative methods to select the number of factors, namely Bai and Ng (2002), Onatski (2010), and Ahn and Horenstein (2013). The criteria studied in the Monte Carlo experiments work equally well in balanced and unbalanced settings, and we could not find clear superiority of one over the other. The additional empirical results, discussed but not reported in the paper, are available on request.

2 Conditional factor model of asset returns

In this section, we consider a conditional linear factor model with time-varying coefficients under an approximate factor structure (Chamberlain and Rothschild (1983)) with a continuum of assets as in GOS. Let \( \mathcal{F}_t \), with \( t = 1, 2, \ldots \), be the information available to investors. Without loss of generality, the continuum of assets is represented by the interval \([0, 1]\). The excess returns \( R_t(\gamma) \) of asset \( \gamma \in [0, 1] \) at dates \( t = 1, 2, \ldots \) satisfy the conditional linear factor model:

\[
R_t(\gamma) = a_t(\gamma) + b_t(\gamma)' f_t + \varepsilon_t(\gamma),
\]

where vector \( f_t \) gathers the values of \( K \) observable factors at date \( t \). The intercept \( a_t(\gamma) \) and factor sensitivities \( b_t(\gamma) \) are \( \mathcal{F}_{t-1} \)-measurable. The error terms \( \varepsilon_t(\gamma) \) have mean zero and are uncorrelated with the factors conditionally on information \( \mathcal{F}_{t-1} \). The conditioning information \( \mathcal{F}_{t-1} \) contains \( Z_{t-1} \) and \( Z_{t-1}(\gamma) \), for all \( \gamma \in [0, 1] \), where the vector of lagged instruments \( Z_{t-1} \in \mathbb{R}^p \) is common to all stocks, the vector of lagged instruments \( Z_{t-1}(\gamma) \in \mathbb{R}^q \) is specific to stock \( \gamma \), and \( Z_{t-1} = \{ Z_t, Z_{t-1}, \ldots \} \). To ensure that cross-sectional limits exist and are invariant to reordering of the assets, we introduce a sampling scheme as in GOS. We formalize it so that observable assets are random draws from an underlying population (Andrews (2005)). In particular, we rely on a sample of \( n \) assets by randomly drawing i.i.d. indices \( \gamma_i \) from the population according to a probability distribution \( G \) on \([0, 1]\). By random sampling, we get a generic random coefficient
panel model (e.g. Hsiao (2003), Chapter 6):

\[ R_{i,t} = x'_{i,t} \beta_i + \varepsilon_{i,t}, \]  

(2)

where \( R_{i,t} = R_t(\gamma_i) \) and the regressors \( x_{i,t} \) of dimension \( d \) includes cross-products of \( f_t, Z_t, \) and \( Z_{i,t-1} = Z_{t-1}(\gamma_i) \). The vector of coefficients \( \beta_i \) is a function of asset specific parameters when defining the dynamics of \( a_{i,t} = a_t(\gamma_i) \) and \( b_{i,t} = b_t(\gamma_i) \) as linear functions of lagged instruments and ruling out asymptotic arbitrage opportunities as detailed in GOS. In matrix notation, for any asset \( i \), we have

\[ R_i = X_i \beta_i + \varepsilon_i, \]  

(3)

where \( R_i \) and \( \varepsilon_i \) are \( T \times 1 \) vectors. Regression (2) contains both explanatory variables that are common across assets (scaled factors) and asset-specific regressors. It includes models with time-invariant coefficients as a particular case. In such a case, the regressor reduces to \( x_t = (1, f'_t)' \) and is common across assets, and the regression coefficient vector is \( \beta_i = (a_i, b'_i)' \) of dimension \( d = K + 1 \).

In available datasets, we do not observe asset returns for all firms at all dates. Thus, we account for the unbalanced nature of the panel through a collection of indicator variables \( I_{i,t} = I_t(\gamma_i) \), for any asset \( i \) at time \( t \). We define \( I_{i,t} = 1 \) if the return of asset \( i \) is observable at date \( t \), and 0 otherwise (Connor and Korajczyk (1987)).

In (2), we treat \( \beta_i \) as a random draw as in GOS. Such a formalisation is key to reconcile finance theory and econometric modelling. It is not for the econometric theory developed below if we treat the linear model (2) as given and not derived from finance theory. The theorems listed in the next sections remain valid for \( \beta_i, i = 1, ..., n \) viewed as a fixed parameter with only minor changes in the statement of the assumptions and proof arguments. This route would not be compatible with subsequent risk premia inferential analysis based on the two-pass regression methodology of GOS.

In order to build the diagnostic criterion for the set of observable factors, we consider the following rival models:

\[ \mathcal{M}_1 : \] the linear regression model (2), where the errors \( \varepsilon_{i,t} \) are weakly cross-sectionally dependent,

and

\[ \mathcal{M}_2 : \] the linear regression model (2), where the errors \( \varepsilon_{i,t} \) satisfy a factor structure.
Under model $M_1$, the observable factors fully capture the systematic risk, and the error terms do not feature pervasive forms of cross-sectional dependence (see Assumption A.3 in Appendix 1). This zero-factor case in the error terms should hold when we choose factors and instruments in a time-varying setting to build the variables $x_{i,t}$, so that their explanatory power achieves weak cross-sectional correlation. Under model $M_2$, the following error factor structure holds

$$\varepsilon_{i,t} = \theta^t h_t + u_{i,t}, \quad (4)$$

where the $m \times 1$ vector $h_t$ includes unobservable (i.e., latent or hidden) factors, and the $u_{i,t}$ are weakly cross-sectionally correlated. The latent factors may include scaled factors to cover latent time-varying factor loadings with common instruments. Such scaled factors may come from mispecification of the functional form of the time-varying betas. Since the factors $h_t$ are unobservable by definition, we cannot tell from the output of the diagnostic criterion whether they are pure or scaled factors. We cannot allow for latent time-varying factor loadings with stock-specific instruments because of identification issues in disentangling time-varying loadings and latent factors. This lack of identification means that we cannot estimate a generic time-varying unobservable structure from the spectral properties of a covariance matrix. A recent proposal in the direction of a functional specification for a time-varying $\theta_{i,t}$ is the Instrumented Principal Components Analysis of Kelly et al. (2017, 2019). They work with linear loading specifications, with balanced panels, and without observable factors. In (4), the $\theta_i$’s and $h_t$’s are also called interactive fixed effects in the panel literature. The $m \times 1$ vector $\theta_i$ corresponds to the factor loadings, and the number $m$ of common factors is assumed unknown. In vector notation, we have:

$$\varepsilon_i = H\theta_i + u_i, \quad (5)$$

where $H$ is the $T \times m$ matrix of unobservable factor values, and $u_i$ is a $T \times 1$ vector.

**Assumption 1** Under model $M_2$: (i) Matrix $\frac{1}{T} \sum_t h_t h_t^t$ converges in probability to a positive definite matrix $\Sigma_h$, as $T \rightarrow \infty$. (ii) $\mu_1 \left( \frac{1}{n} \sum_i \theta_i \theta_i^t \right) \geq C$, w.p.a. 1 as $n \rightarrow \infty$, for a constant $C > 0$, where $\mu_1 (\cdot)$ denotes the largest eigenvalue of a symmetric matrix.

Assumption 1 (i) is a standard condition in linear latent factor models (see Assumption A in Bai and Ng (2002)) and we can normalize matrix $\Sigma_h$ to be the identity matrix $I_m$ for identification. Assumption 1 (ii)
requires that at least one factor in the error terms is strong. It is satisfied if the second-order matrix of the loadings \( \frac{1}{n} \sum_i \theta_i \theta_i' \) converges in probability to a positive definite matrix (see Assumption B in Bai and Ng (2002)).

We work with the condition:

\[
E[x_{i,t} h_t'] = 0, \quad \forall i,
\]

that is, orthogonality between latent factors and observable regressors for all stocks. This condition allows us to follow a two-step approach: we first regress stock returns on observable regressors to compute residuals, and then search for latent common factors in the panel of residuals (see next section). We can interpret condition (6) via an analogy with the partitioned regression:

\[
Y = X_1 \beta_1 + X_2 \beta_2 + \epsilon.
\]

The Frisch-Waugh-Lovell Theorem (Frisch and Frederick (1933), Lovell (1963)) states that the ordinary least squares (OLS) estimate of \( \beta_2 \) is identical to the OLS estimate of \( \beta_2 \) in the regression \( M_{X_1} Y = M_{X_1} X_2 \beta_2 + \eta \), where \( M_{X_1} = I_n - X_1 (X_1' X_1)^{-1} X_1' \). Condition (6) is tantamount to the orthogonality condition \( X_1' X_2 = 0 \) ensuring that we can estimate \( \beta_2 \) from regressing the residuals \( M_{X_1} Y \) on \( X_2 \) only, instead of the residuals \( M_{X_1} X_2 \) coming from the regression of \( X_2 \) on \( X_1 \). When condition (6) is not satisfied, joint estimation of regression coefficients, latent factor betas and factor values is required (see e.g. Bai (2009), Moon and Weidner (2015) in a model with homogeneous regression coefficients \( \beta_i = \beta \) for all \( i \), and Ando and Bai (2015) for heterogeneous \( \beta_i \) in balanced panels). If the regressors are common across stocks, i.e., \( x_{i,t} = x_t \), we can obtain condition (6) by transformation of the latent factors. It simply corresponds to an identification restriction on the latent factors, and is then not an assumption when we allow for different \( \beta_i \)'s. If the regressors are stock-specific, ensuring orthogonality between the latent factors \( h_t \) and the observable regressors \( x_{i,t} \) for all \( i \) is more than an identification restriction. It requires an additional assumption where we decompose common and stock-specific components in the regressors vector by writing \( x_{i,t} = (x_t', \tilde{x}_{i,t})' \), where \( x_t := (\text{vech}[Z_{t-1} Z_{t-1}'], f_t' \otimes Z_{t-1}')' \) and \( \tilde{x}_{i,t} := (Z_{i,t-1}' \otimes Z_{i,t-1}', f_t' \otimes Z_{i,t-1}')' \).

**Assumption 2** The best linear prediction of the unobservable factor \( EL(h_t | \{x_{i,t}, \ i = 1, 2, \ldots\}) \) is independent of \( \{\tilde{x}_{i,t}, \ i = 1, 2, \ldots\} \).

Assumption 2 amounts to contemporaneous Granger non-causality from the stock-specific regressors to the latent factors, conditionally on the common regressors. Assumption 2 is verified e.g. if the latent...
factors are independent of the lagged stock-specific instruments, conditional on the observable factors and the lagged common instruments (see Appendix 5 of the online supplementary materials for a derivation). We keep Assumption 2 as a maintained assumption on the factor structure under $M_2$. Under Assumption 2, $EL(h_t|\{x_{i,t}, i = 1, 2, \ldots\}) =: \Psi x_t$ is a linear function of $x_t$. Therefore, by transformation of the latent factor $h_t \rightarrow h_t - \Psi x_t$, we can assume that $EL(h_t|\{x_{i,t}, i = 1, 2, \ldots\}) = 0$, without loss of generality. This condition implies (6). We use Assumption 2 and Assumption A.6 to control expectations of time-series cross-products of $x_{i,t}h_t'$ (see the discussion of the regularity conditions and Lemma 3 below).

3 Diagnostic criterion

In this section, we provide the diagnostic criterion that checks whether the error terms are weakly cross-sectionally correlated or share at least one common factor. To compute the criterion, we estimate the generic panel model (2) by OLS applied asset by asset, and we get estimators $\hat{\beta}_i = \hat{Q}_{x,i}^{-1} \frac{1}{T_i} \sum I_{i,t} x_{i,t} R_{i,t}$, for $i = 1, \ldots, n$, where $\hat{Q}_{x,i} = \frac{1}{T_i} \sum I_{i,t} x_{i,t} x_{i,t}'$. We get the residuals $\hat{\varepsilon}_{i,t} = R_{i,t} - x_{i,t}' \hat{\beta}_i$, where $\hat{\varepsilon}_{i,t}$ is observable only if $I_{i,t} = 1$. In available panels, the random sample size $T_i$ for asset $i$ can be small, and the inversion of matrix $\hat{Q}_{x,i}$ can be numerically unstable. To avoid unreliable estimates of $\beta_i$, we apply a trimming approach as in GOS. We define $1_i = 1 \left\{ CN(\hat{Q}_{x,i}) \leq \chi_{1,T} ; \tau_{i,T} \leq \chi_{2,T} \right\}$, where $CN(\hat{Q}_{x,i}) = \sqrt{\mu_1(\hat{Q}_{x,i})/\mu_d(\hat{Q}_{x,i})}$ is the condition number of the $d \times d$ matrix $\hat{Q}_{x,i}$, $\mu_d(\hat{Q}_{x,i})$ is its smallest eigenvalue and $\tau_{i,T} = T/T_i$. The two sequences $\chi_{1,T} > 0$ and $\chi_{2,T} > 0$ diverge asymptotically (Assumption A.10). The first trimming condition $\{ CN(\hat{Q}_{x,i}) \leq \chi_{1,T} \}$ keeps in the cross-section only assets for which the time-series regression is not too badly conditioned. A too large value of $CN(\hat{Q}_{x,i})$ indicates multicollinearity problems and ill-conditioning (Belsley et al. (2004), Greene (2008)). The second trimming condition $\{ \tau_{i,T} \leq \chi_{2,T} \}$ keeps in the cross-section only assets for which the time series is not too short. We also use both trimming conditions in the proofs of the asymptotic results. The theoretical results below remain unaffected if we use WLS with value weighting (as sometimes used in empirical applications).

We consider the following diagnostic criterion:

$$\xi = \mu_1 \left( \frac{1}{nT} \sum i \chi \hat{\varepsilon}_i \hat{\varepsilon}_i' \right) - g(n, T),$$

(7)
where the vector \( \bar{\varepsilon}_i \) of dimension \( T \) gathers the values \( \bar{\varepsilon}_{i,t} = I_{i,t} \hat{\varepsilon}_{i,t} \), the penalty \( g(n, T) \) is such that \( g(n, T) \to 0 \) and \( C_{n,T}^2 g(n, T) \to \infty \), when \( n, T \to \infty \), for \( C_{n,T}^2 = \min\{n, T\} \). Bai and Ng (2002) consider several simple potential candidates for the penalty \( g(n, T) \). We discuss them in Section 5. In vector \( \bar{\varepsilon}_i \), the unavailable residuals are replaced by zeros. We use the following assumption on \( n \) and \( T \).

**Assumption 3** The cross-sectional dimension \( n \) and time series dimension \( T \) are such that \( n = O(T^{1/2}) \), \( \gamma > 0 \), and \( T = O(n^{\gamma}) \), \( \gamma \in (0, 1] \).

The following model selection rule explains our choice of the diagnostic criterion (7) for approximate factor structure in large unbalanced cross-sectional datasets.

**Proposition 1** Model selection rule: We select \( \mathcal{M}_1 \) if \( \xi < 0 \), and we select \( \mathcal{M}_2 \) if \( \xi > 0 \). Under Assumptions 1-3 and Assumptions A.1-A.10, the model selection rule is consistent since (a) \( \Pr (\xi < 0 \mid \mathcal{M}_1) \to 1 \), and (b) \( \Pr (\xi > 0 \mid \mathcal{M}_2) \to 1 \), when \( n, T \to \infty \).

Proposition 1 characterizes a model selection rule which treats both models symmetrically and selects asymptotically the correct model with probability approaching 1. The model selection rule is valid also from a Bayesian perspective. Indeed, parts (a) and (b) imply by Bayes Theorem that \( \Pr (\mathcal{M}_1 | \xi < 0) = \Pr (\xi < 0 | \mathcal{M}_1) \Pr (\mathcal{M}_1) / [\Pr (\xi < 0 | \mathcal{M}_1) \Pr (\mathcal{M}_1) + \Pr (\xi < 0 | \mathcal{M}_2) \Pr (\mathcal{M}_2)]^{-1} \to 1 \), as \( n, T \to \infty \). Similarly, we have \( \Pr (\mathcal{M}_2 | \xi > 0) \to 1 \). The diagnostic criterion in Proposition 1 is not a testing procedure since we do not use a critical region based on an asymptotic distribution and a chosen significance level. The zero threshold corresponds to an implicit critical value yielding a test size asymptotically equal to zero since \( \Pr (\xi < 0 | \mathcal{M}_1) \to 1 \). The selection procedure is conservative in diagnosing zero factor by construction. We do not allow type I error under \( \mathcal{M}_1 \) asymptotically, and really want to ensure that there is no omitted factor as required in the APT setting. This also means that we will not suffer from false discoveries related to a multiple testing problem (see e.g. Barras et al. (2010), Harvey et al. (2016)) in our empirical application where we consider a large variety of factor models on monthly and quarterly data. However, a possibility to achieve \( p \)-values is to use a randomisation procedure as in Trapani (2018) (see Bandi and Corradi (2014) and Corradi and Swanson (2006) for recent applications in econometrics). This type of procedure controls for an error of the first type, conditional on the information provided by the sample and under a randomness induced by auxiliary experiments.
The proof of Proposition 1 shows that the largest eigenvalue in (7) vanishes at a faster rate (Lemma 1 in Appendix A.2.1) than the penalization term under \( M_1 \) when \( n \) and \( T \) go to infinity. Under \( M_1 \), we expect a vanishing largest eigenvalue because of a lack of a common signal in the error terms. The negative penalizing term \(-g(n, T)\) dominates in (7), and this explains why we select the first model when \( \xi \) is negative. On the contrary, the largest eigenvalue remains bounded from below away from zero (Lemma 4 in Appendix A.2.1) under \( M_2 \) when \( n \) and \( T \) go to infinity. Under \( M_2 \), we have at least one non-vanishing eigenvalue because of a common signal due to omitted factors. The largest eigenvalue dominates in (7), and this explains why we select the second model when \( \xi \) is positive. We can interpret the criterion (7) as the adjusted gain in fit including a single additional (unobservable) factor in model \( M_1 \). We can rewrite (7) as \( \xi = SS_0 - SS_1 - g(n, T) \), where \( SS_0 = \frac{1}{nT} \sum_i \sum_t \hat{\chi}_i \hat{\epsilon}_{i,t}^2 \) is the sum of squared errors and \( SS_1 = \min \frac{1}{nT} \sum_i \sum_t \hat{\chi}_i (\hat{\epsilon}_{i,t} - \theta_i h_t)^2 \), where the minimization is w.r.t. the vectors \( H \in \mathbb{R}^T \) of factor values and \( \Theta = (\theta_1, ..., \theta_n)' \in \mathbb{R}^n \) of factor loadings in a one-factor model, subject to the normalization constraint \( H' H T = 1 \). Indeed, the largest eigenvalue \( \mu_1 \left( \frac{1}{nT} \sum_i \hat{\chi}_i \hat{\epsilon}_{i,t} \hat{\epsilon}_i' \right) \) corresponds to the difference between \( SS_0 \) and \( SS_1 \). Furthermore, the criterion \( \xi \) is equal to the difference of the penalized criteria for zero- and one-factor models defined in Bai and Ng (2002) applied on the residuals. Indeed, \( \xi = PC(0) - PC(1), \) where \( PC(0) = SS_0, \) and \( PC(1) = SS_1 + g(n, T). \)

Lemma 1 in Appendix A.2.1 gives an asymptotic upper bound on the largest eigenvalue of a symmetric matrix based on similar arguments as in Geman (1980), Yin et al. (1988), and Bai and Yin (1993) without exploiting distributional results from random matrix theory valid when \( n \) is comparable with \( T \). This exemplifies a key difference with the proportional asymptotics used in Onatski (2010) or Ahn and Horenstein (2013) for balanced panel without observable factors. In Proposition 1, when \( \tau < 1 \), the condition \( T/n = o(1) \) agrees with the “large \( n \), small \( T \)” case that we face in the empirical application (ten thousand individual stocks monitored over forty-five years of either monthly, or quarterly, returns). Another key difference w.r.t. the available literature is the handling of unbalanced panels. We need to address explicitly the presence of the observability indicators \( I_{i,t} \) and the trimming devices \( \chi_i \) in the proofs of the asymptotic results.

The recent literature on the properties of the two-pass regressions for fixed \( n \) and large \( T \) shows that the
presence of useless factors (Kan and Zhang (1999a,b), Gospodinov et al. (2014)) or weak factor loadings (Kleibergen (2009)) does not affect the asymptotic distributional properties of factor loading estimates, but alters the ones of the risk premia estimates. Useless factors have zero loadings, and weak loadings drift to zero at rate \( 1/\sqrt{T} \). The vanishing rate of the largest eigenvalue of the empirical cross-sectional covariance matrix of the residuals does not change if we face useless factors or weak factor loadings in the observable factors under \( \mathcal{M}_1 \). The same remark applies under \( \mathcal{M}_2 \). Hence the selection rule remains the same since the probability of taking the right decision still approaches 1. If we have a number of useless factors or weak factor loadings strictly smaller than the number \( m \) of the omitted factors under \( \mathcal{M}_2 \), this does not impact the asymptotic rate of the diagnostic criterion if Assumption 1 holds. If we only have useless factors in the omitted factors under \( \mathcal{M}_2 \), we face an identification issue. Assumption 1 (ii) is not satisfied. We cannot distinguish such a specification from \( \mathcal{M}_1 \) since it corresponds to a particular approximate factor structure.

Again the selection rule remains the same since the probability of taking the right decision still approaches 1. Finally, let us study the case of only weak factor loadings under \( \mathcal{M}_2 \). We consider a simplified setting: 

\[ R_{i,t} = x'_{i,t} \beta_i + \varepsilon_{i,t}, \]

where \( \varepsilon_{i,t} = \theta_i h_t + u_{i,t} \) has only one factor with a weak factor loading, namely \( m = 1 \) and \( \theta_i = \bar{\theta}_i / T^c \) with \( c > 0 \). Let us assume that \( \frac{1}{n} \sum \theta_i^2 \) is bounded from below away from zero (see Assumption 1 (ii)) and bounded from above. By the properties of the eigenvalues of a scalar multiple of a matrix, we deduce that 

\[
c_1 T^{-2c} - g(n, T) + O_p \left( C^{-2}_{nT} + \tilde{\chi}_T T^{-1} \right) \leq \xi \leq c_2 T^{-2c} - g(n, T) + O_p \left( C^{-2}_{nT} + \tilde{\chi}_T T^{-1} \right),
\]

where we define \( \tilde{\chi}_T = \chi_{1,T}^2 / \chi_{2,T}^2 \). To conclude \( \mathcal{M}_2 \), we need that \( C^{-2}_{nT} + \tilde{\chi}_T T^{-1} \) and the penalty \( g(n, T) \) vanish at a faster rate than \( T^{-2c} \), namely \( C^{-2}_{nT} + \tilde{\chi}_T T^{-1} = o \left( T^{-2c} \right) \) and \( g(n, T) = o \left( T^{-2c} \right) \). To conclude \( \mathcal{M}_1 \), we need that \( g(n, T) \) is the dominant term, namely \( T^{-2c} = o \left( g(n, T) \right) \) and \( C^{-2}_{nT} + \tilde{\chi}_T T^{-1} = o \left( g(n, T) \right) \).

As an example, let us take \( g(n, T) = T^{-1} \log T \) and \( n = T^{\gamma / 2} \) with \( \gamma < 1 \), and assume that the trimming is such that \( \tilde{\chi}_T = o \left( \log T \right) \). Then, we conclude \( \mathcal{M}_2 \) if \( c < 1 / 2 \) and \( \mathcal{M}_1 \) if \( c > 1 / 2 \). This means that detecting a weak factor loading structure is difficult if \( c \) is not sufficiently small. The factor loadings should drift to zero not too fast to conclude \( \mathcal{M}_2 \). Otherwise, we cannot distinguish it asymptotically from weak cross-sectional correlation. When \( n \) is comparable with \( T \) (and without observable factors), the case
$c = 1/2$ corresponds to the setting of weakly influential factors considered in Onatski (2012, 2015). Under that asymptotic scheme, Onatski (2012) shows that the Principal Components estimator is inconsistent, and remarks that there cannot exist a procedure allowing to consistently estimate the true number of latent factors.

Several papers in the empirical asset pricing literature focus on distinguishing between useful, useless and redundant factors starting from different points of view. Bryzgalova (2016) develops a shrinkage-based estimator that identify the weak factors (i.e., factors that do not correlate with the assets) and ensure consistent and normality to the estimates of the risk premia. Feng et al. (2017) propose a model-selection method to evaluate the risk prices of observable factors. Freyberger et al. (2017) propose a nonparametric method to determine which firm characteristics provide incremental information for the cross section of expected returns. Kozak et al. (2018) use model selection techniques to identify characteristics portfolios with a good explanatory power for returns. These papers do not deal with the identification of systematic factors for which the errors are weakly cross-sectionally correlated. The model selection procedure is not able to answer at our key question on the presence of omitted factors in the chosen specification.

4 Determining the number of factors

In the previous section, we have studied a diagnostic criterion to check whether the error terms are weakly cross-sectionally correlated or share at least one unobservable common factor. This section aims at answering: do we have one, two, or more omitted factors? The design of the diagnostic criterion to check whether the error terms share exactly $k$ unobservable common factors or share at least $k + 1$ unobservable common factors follows the same mechanics. We consider the following rival models:

\[ \mathcal{M}_1 (k) : \] the linear regression model (2), where the errors ($\varepsilon_{i,t}$) satisfy a factor structure with exactly $k$ unobservable factors,

and

\[ \mathcal{M}_2 (k) : \] the linear regression model (2), where the errors ($\varepsilon_{i,t}$) satisfy a factor structure with at least $k + 1$ unobservable factors.
The above definitions yield $M_1 = M_1(0)$ and $M_2 = M_2(0)$.

**Assumption 4** Under model $M_2(k)$, we have $\mu_{k+1}\left(\frac{1}{n} \sum_i \theta_i \theta_i'\right) \geq C$, w.p.a. 1 as $n \to \infty$, for a constant $C > 0$, where $\mu_{k+1}(\cdot)$ denotes the $(k+1)$-th largest eigenvalue of a symmetric matrix.

Models $M_1(k)$ and $M_2(k)$ with $k \geq 1$ are subsets of model $M_2$. Hence, Assumption 1 (i) guarantees the convergence of matrix $\frac{1}{T} \sum_t h_t h_t'$ to a positive definite $k \times k$ matrix under $M_1(k)$, and to a positive definite $m \times m$ matrix under $M_2(k)$, with $m \geq k + 1$. Assumption 4 requires that there are at least $k + 1$ strong factors under $M_2(k)$.

The diagnostic criterion exploits the $(k + 1)$th largest eigenvalue of the empirical cross-sectional covariance matrix of the residuals:

$$\xi(k) = \mu_{k+1}\left(\frac{1}{nT} \sum_i \mathbf{1}_i^T \bar{\varepsilon}_i \bar{\varepsilon}_i'\right) - g(n, T).$$

As discussed in Ahn and Horenstein (2013) (see also Onatski (2015)) for balanced panels, we can rewrite (8) as $\xi(k) = SS_k - SS_{k+1} - g(n, T)$ where $SS_k = \min_{H, \Theta} \frac{1}{nT} \sum_t \sum_i \mathbf{1}_i^T (\bar{\varepsilon}_{i,t} - \theta_i' h_t)^2$ and the minimization is w.r.t. $H \in \mathbb{R}^{T \times k}$ and $\Theta = (\theta_1, ..., \theta_n)' \in \mathbb{R}^{n \times k}$. The criterion $\xi(k)$ is equal to the difference of the penalized criteria for $k$ and $(k+1)$-factor models defined in Bai and Ng (2002) applied on the residuals. Indeed, $\xi(k) = PC(k) - PC(k+1)$, where $PC(k) = SS_k + kg(n, T)$ and $PC(k + 1) = SS_{k+1} + (k + 1)g(n, T)$. The following model selection rule extends Proposition 1.

**Proposition 2** Model selection rule: We select $M_1(k)$ if $\xi(k) < 0$, and we select $M_2(k)$ if $\xi(k) > 0$. Under Assumptions 1(i), 2-4, and Assumptions A.1-A.11, the model selection rule is consistent since (a) $Pr[\xi(k) < 0|M_1(k)] \to 1$ and (b) $Pr[\xi(k) > 0|M_2(k)] \to 1$, when $n, T \to \infty$.

The proof of Proposition 2 is more complicated than the proof of Proposition 1. We need additional arguments to derive an asymptotic upper bound when we look at the $(k + 1)$th eigenvalue of a symmetric matrix (Lemma 5 in Appendix A.2.2), and this further complexity explains why we have developed Proposition 1 as a special case. We rely on the Courant-Fischer min-max theorem and Courant-Fischer formula (see beginning of Appendix 2) which represent eigenvalues as solutions of constrained quadratic optimization.
problems. We cannot directly exploit standard inequalities or bounds associated to a norm (as in the proof of Proposition 1) when we investigate the asymptotic behavior of the spectrum beyond its largest element. We know that the largest eigenvalue \( \mu_1(A) \) of a symmetric positive semi-definite matrix \( A \) is equal to its operator norm. There is no such useful norm interpretation for the smaller eigenvalues \( \mu_k(A), k \geq 2 \). We cannot directly exploit standard inequalities or bounds associated to a norm when we investigate the asymptotic behavior of the spectrum beyond its largest element. We cannot either exploit distributional results from random matrix theory since we also allow for \( T/n = o(1) \). The slow convergence rate \( \sqrt{T} \) for the individual estimates \( \hat{\beta}_i \) also complicates the proof. In the presence of homogeneous regression coefficients \( \beta_i = \beta \) for all \( i \), the estimate \( \hat{\beta} \) in Bai (2009) and Moon and Weidner (2015) has a fast convergence rate \( \sqrt{nT} \). In that case, controlling for the estimation error in \( \hat{\epsilon}_{i,t} = \epsilon_{i,t} + x'_{i,t}(\beta - \hat{\beta}) \) is straightforward due to the small asymptotic contribution of \( (\beta - \hat{\beta}) \). Hence our results also apply to diagnose the absence of omitted interactive effects before applying a difference-in-differences procedure to avoid bias. The approach of Onatski (2010) requires the convergence of the upper edge of the spectrum (i.e., the first \( k \) largest eigenvalues of the covariance matrix, with \( k/T = o(1) \)) to a constant, while the approach of Ahn and Horenstein (2013) requires an asymptotic lower bound on the eigenvalues. Extending these approaches for residuals of an unbalanced panel when \( T/n = o(1) \) looks challenging.

We can use the results of Proposition 2 in order to estimate the number of unobservable factors. It suffices to choose the minimum \( k \) such that \( \xi(k) < 0 \). The next proposition states the consistency of that estimate even in the presence of a degenerate distribution of the eigenvalues.

**Proposition 3** Let \( \hat{k} = \min \{ k = 0, 1, \ldots, T - 1 : \xi(k) < 0 \} \), where \( \hat{k} = T \) if \( \xi(k) \geq 0 \) for all \( k \leq T - 1 \). Then, under Assumptions 1(i), 2-4, and Assumptions A.1-A.11, and under \( M_1(k_0) \), we have \( P[\hat{k} = k_0] \to 1 \), as \( n, T \to \infty \).

In Proposition 3, we do not need to give conditions on the growth rate of the maximum possible number \( k_{max} \) of factors as in Onatski (2010) and Ahn and Horenstein (2013). We believe that this is a strong advantage since there are many possible choices for \( k_{max} \) and the estimated number of factors is sometimes sensitive to the choice of \( k_{max} \) (see the simulation results in those papers). In the supplementary materials on our author websites, we show that our procedure selects the right number of factors with an observed 100 percent probability in most Monte Carlo experiments when \( n \) is comparable or much larger than \( T \).
5 Implementation and graphical diagnostic tool

In this section, we discuss how we can implement the model selection rule in practice and design simple graphical diagnostic tools to determine the number of unobservable factors (see Figures 1-2 in the next section). First, recognize that

$$\hat{\sigma}^2 = \frac{1}{nT} \sum_i \sum_t \chi_i \bar{\epsilon}_{i,t} = tr \left( \frac{1}{nT} \sum_i \chi_i \bar{\epsilon}_{i} \bar{\epsilon}_{i}' \right) = \sum_{j=1}^{T} \mu_j \left( \frac{1}{nT} \sum_i \chi_i \bar{\epsilon}_{i} \bar{\epsilon}_{i}' \right).$$

The ratio \(\mu_j \left( \frac{1}{nT} \sum_i \chi_i \bar{\epsilon}_{i} \bar{\epsilon}_{i}' \right) / \hat{\sigma}^2\) gauges the contribution of the \(j\)th eigenvalue in percentage of the variance \(\hat{\sigma}^2\) of the residuals. Similarly, the sum \(\sum_{j=1}^{k} \mu_j \left( \frac{1}{nT} \sum_i \chi_i \bar{\epsilon}_{i} \bar{\epsilon}_{i}' \right) / \hat{\sigma}^2\) gauges the cumulated contribution of the \(k\) largest eigenvalues in percentage of \(\hat{\sigma}^2\). From Proposition 2, when all eigenvalues in that sum are larger than \(g(n, T)\), this is equal to the percentage of \(\hat{\sigma}^2\) explained by the \(k\) unobservable factors. Therefore, we suggest to work in practice with rescaled eigenvalues which are more informative. We can easily build a scree plot where we display the rescaled eigenvalues \(\mu_j \left( \frac{1}{nT} \sum_i \chi_i \bar{\epsilon}_{i} \bar{\epsilon}_{i}' \right) / \hat{\sigma}^2\) in descending order versus the number of omitted factors \(k\), and use the horizontal line set at \(g(n, T) / \hat{\sigma}^2\) as the cut-off point to determine the number of omitted factors. This yields exactly the same choice as the one in Proposition 3. The asymptotic validity of the selection rule in unaffected since \(\hat{\sigma}^2\) converges to a strictly positive constant when \(n, T \to \infty\). Such a scree plot helps to visually assess which unobservable factors, if needed, explain most of the variability in the residuals. We can set \(g(n, T) / \hat{\sigma}^2 = \left( \frac{n + T}{nT} \right) \ln \left( \frac{nT}{n + T} \right)\) following a suggestion in Bai and Ng (2002). Those authors propose two other potential choices \(\left( \frac{n + T}{nT} \right) \ln C_{nT}^2\) and \(\left( \frac{\ln C_{nT}^2}{C_{nT}^2} \right)\). In our empirical application, \(n\) is much larger than \(T\), and they yield identical results.

From Section 3, we know that \(\xi = SS_0 - SS_1 - g(n, T)\). Given such an interpretation in terms of sums of squared errors, we can think about another diagnostic criterion based on a logarithmic version \(\hat{\xi}\) as in Corollary 2 of Bai and Ng (2002). The second diagnostic criterion is

$$\hat{\xi} = \ln (\hat{\sigma}^2) - \ln \left( \hat{\sigma}^2 - \mu_1 \left( \frac{1}{nT} \sum_i \chi_i \bar{\epsilon}_{i} \bar{\epsilon}_{i}' \right) \right) - g(n, T).$$

We get \(\hat{\sigma}^2 = SS_0\), and \(\hat{\xi} = \ln(\hat{SS}_0/\hat{SS}_1) - g(n, T)\) is equal to the difference of \(IC (0)\) and \(IC (1)\) criteria in Bai and Ng (2002). Then, the model selection rule is the same as in Proposition 1 with \(\hat{\xi}\) substituted for \(\xi\).

For the logarithmic version, Bai and Ng (2002) suggest to use the penalty
\[ g(n, T) = \left( \frac{n + T}{n} \right) \ln \left( \frac{nT}{n + T} \right) \] since the scaling by \( \hat{\sigma}^2 \) is implicitly performed by the logarithmic transformation of \( SS_0 \) and \( SS_1 \). Since, from Equation (9), \( \xi = \ln \left( \frac{1}{1 - \mu_1} \left( \frac{1}{nT} \sum_i 1_i^X \bar{\varepsilon}_i \bar{\varepsilon}_i' / \hat{\sigma}^2 \right) \right) \)

\(-g(n, T) \) and \( x \) is close to \( \ln(1/(1 - x)) \) for a small \( x \), we see that a rule based on the rescaled criterion \( \xi / \hat{\sigma}^2 \) is closely related to the logarithmic version when the rescaled eigenvalue is small. This further explains why we are in favour of working in practice with rescaled eigenvalues.

Prior to computation of the eigenvalues, Bai and Ng (2002) advocate each series to be demeaned and standardized to have unit variance (see also Section 4 in King et al. (1994)). In our setting, each time series of residuals \( \bar{\varepsilon}_{i,t} \) have zero mean by construction, and we also standardize them to have unit variance over the sample of \( T \) observations before computing the eigenvalues. Working with \( \bar{\varepsilon}_{i,t} = \bar{\varepsilon}_{i,t} / \sqrt{T} \sum_t \bar{\varepsilon}_{i,t}^2 \) ensures that all series of residuals have a common scale of measurement and improves the stability of the information extracted from the multivariate time series (see e.g. Pena and Poncela (2006)). Since \( \text{tr} \left( \sum_i 1_i^X \bar{\varepsilon}_i \bar{\varepsilon}_i' \right) = nX^T \) with \( nX^i = \sum_i 1_i^X \), we suggest to work with the normalised matrix \( \frac{1}{nX^T} \sum_i 1_i^X \bar{\varepsilon}_i \bar{\varepsilon}_i' \), so that the variance \( \frac{1}{nX^T} \sum_i \sum_t 1_i^X \bar{\varepsilon}_{i,t} \bar{\varepsilon}_{i,t}' \) of the scaled residuals is 1 by construction, and we can interpret \( \mu_j \left( \frac{1}{nX^T} \sum_i 1_i^X \bar{\varepsilon}_i \bar{\varepsilon}_i' \right) \) directly as percentage of the variance of the normalised residuals.

From Johnstone (2001), we know that for a matrix of residuals, all of whose entries are independent standard Gaussian variates in a balanced panel, the distribution of the largest eigenvalue of the corresponding Wishart variable suitably normalized approaches the Tracy-Widom law of order 1 under proportional asymptotics (see Onatski (2009) for the assumption of Gaussian errors). That result implies that, for such standard Gaussian residuals, the largest eigenvalue that we compute should be approximately \( 1/T \) if \( T \) is smaller than \( n \) (see also Geman (1980)) without the need to rely on a scaling by an estimated variance \( \hat{\sigma}^2 \). This further explains why we are in favor of working with standardised residuals, so that we are as close as possible to a standardized Gaussian reference model. This is akin to use the standard rule of thumb based on a Gaussian reference model in nonparametric density estimation (Silverman (1986)). We know the rate of convergence of the kernel density estimate but need an idea of the constant to use that information for practical bandwidth choice. In our setting, we can set the constant to one, when we face independent standard Gaussian residuals. The Gaussian reference model also suggests to use the penalisa-
tion \( g(n, T) = \left( \frac{\sqrt{n} + \sqrt{T}}{nT} \right)^2 \ln \left( \frac{nT}{\sqrt{n} + \sqrt{T}} \right)^2 \). This is our choice in the empirical section with \( n^\chi \) substituted for \( n \), and a data-driven constant substituted for the known constant 1 of the Gaussian reference model (see the Monte Carlo section for a detailed explanation of the selection method based on the proposal of Alessi et al. (2010); see also Hallin and Liška (2007) in the general dynamic factor model). We show the good performance of such a rule in the Monte Carlo results for unbalanced panels (as already observed by Hallin and Liška (2007) and Alessi et al. (2010) for balanced panels). We are not aware of a general explicit characterisation of the limit distribution of the largest eigenvalue, and hence of the constant. Bao et al. (2015) show the universality of the Tracy-Widom law for a balanced setting with \( n \) and \( T \) comparable and independent entries.

Finally, we can also investigate the ratio \( \mu_j^2 \left( \frac{1}{nT} \sum_i 1_{\chi} \bar{\varepsilon}_i \bar{\varepsilon}'_i \right) / \sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i 1_{\chi} \bar{\varepsilon}_i \bar{\varepsilon}'_i \right) \) and the cumulated contribution \( \sum_{j=1}^k \mu_j^2 \left( \frac{1}{nT} \sum_i 1_{\chi} \bar{\varepsilon}_i \bar{\varepsilon}'_i \right) / \sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i 1_{\chi} \bar{\varepsilon}_i \bar{\varepsilon}'_i \right) \). The denominator corresponds to the square of the Frobenius (or Hilbert-Schmidt) norm of the matrix \( \frac{1}{nT} \sum_i 1_{\chi} \bar{\varepsilon}_i \bar{\varepsilon}'_i \) since the sum of the squared eigenvalues of a positive semidefinite symmetric matrix \( A = (a_{ij}) \) corresponds to \( tr(A^t A) = \sum_{i,j} a_{ij}^2 \). Those quantities measure the contributions of the omitted factors in terms of the off-diagonal terms (correlation part) in addition to the diagonal terms (residual variance). Here we follow Fiorentini and Sentana (2015, pages 158-159) who prefer to look at the fraction of the Frobenius norm instead of the usual fraction of the trace of the sample covariance matrix to judge the representativeness of principal components. King et al. (1994) use the Frobenius norm to decompose the sample covariance of residuals of a Vector Autoregressive (VAR) model and obtain starting values for maximum likelihood estimation of the parameters of a factor model for the error terms. A selection rule based on the squared eigenvalues being above or below the squared penalty delivers the same diagnostic, but helps to gauge the impact on correlation explanation by the omitted factors.
6 Empirical results

In this section, we compute the diagnostic criteria and the number of omitted factors using a large variety of combinations of financial and macroeconomic factors. We estimate linear factor models using monthly and quarterly data from January 1968 to December 2011.

6.1 Factor models and data description

We consider several linear factor models that involve financial and macroeconomic variables. Let us start with the financial specifications listed in Table 1. We estimate these linear specifications using monthly data. We proxy the risk free rate with the monthly 30-day T-bill beginning-of-month yield. The three factors of Fama and French (1993) are the monthly excess return $r_{m,t}$ on CRSP NYSE/AMEX/Nasdaq value-weighted market portfolio over the risk free rate, and the monthly returns on zero-investment factor-mimicking portfolios for size and book-to-market, denoted by $r_{smb,t}$ and $r_{hml,t}$. The monthly returns on portfolio for momentum is denoted by $r_{mom,t}$ (Carhart (1997)). The two operative profitability factors of Fama and French (2015) are the difference between monthly returns on diversified portfolios with robust and weak profitability and investments, and with low and high investment stocks, denoted by $r_{rmw,t}$ and $r_{cma,t}$. We have downloaded the time series of these factors from the website of Kenneth French. We denote the monthly returns of size, investment, and profitability portfolios introduced by Hou et al. (2015) by $r_{me,t}$, $r_{I/A,t}$ and $r_{ROE,t}$ (see also Hou et al. (2014)). Furthermore, we include quality minus junk ($qmj_t$) and bet against beta ($bab_t$) factors as described in Asness et al. (2019) and Frazzini and Pedersen (2014). The factor return $qmj_t$ is the average return on the two high quality portfolios minus the average return on the two low quality (junk) portfolios. The bet against beta factor is a portfolio that is long low-beta securities and short high-beta securities. We have downloaded these data from the website of AQR. As additional specifications, we consider the two reversal factors which are monthly returns on portfolios for short-term and long-term reversals from the website of Kenneth French. Besides, the monthly returns of industry-adjusted value, momentum and profitability factors are available from the website of Robert Novy-Marx (see Novy-Marx (2013)). We also include the three liquidity-related factors of Pastor and Stambaugh (2002) that consist of monthly liquidity level, traded liquidity, and the innovation in aggregate liquidity. We have downloaded them from the website of Lubos Pastor.
In Table 2, we list the linear factor specifications that involve financial and macroeconomic variables. We estimate these specifications using quarterly data. We consider the aggregate consumption growth $c_{g_t}$ for the CCAPM (Lucas (1978), Breeden (1979)) and the Epstein and Zin (1989) model (see also Epstein and Zin (1991)), the durable and nondurable-consumption growth rate introduced by Yogo (2006) and denoted by $d_{cg_t}$ and $n_{d cg_t}$. The investment factors used in Li et al. (2006) track the changes in the gross private investment for households, for non-financial corporate and for non-financial non-corporate firms, and are denoted by $d_{hh_t}$, $d_{cor p_t}$, and $d_{n cor p_t}$. Finally, we consider the five factors of Chen et al. (1986) available from the website of Laura Xiaolei Liu. Those factors are the growth rate of industrial production $m_{pt}$, the unexpected inflation $u_{it}$, the change in the expected inflation $d_{eit}$, the term spread $u_{ts t}$, proxied by the difference between yields on 10-year Treasury and 3-month T-bill, and the default premia $u_{pr_t}$, proxied by the yield difference between Moody’s Baa-rated and Aaa-rated corporate bonds.

To account for time-varying coefficients, we consider two conditional specifications:

(i) $Z_{t-1} = (1, div_{Y_{t-1}})'$ and (ii) $Z_{t-1} = (1, div_{Y_{t-1}})'$, $Z_{it-1} = bm_{it-1}$, where $div_{Y_{t-1}}$ is the lagged dividend yield and the asset specific instrument $bm_{it-1}$ corresponds to the lagged book-to-market equity of firm $i$. We compute the firm characteristic from Compustat as in the appendix of Fama and French (2008). We refer to Avramov and Chordia (2006) for convincing theoretical and empirical arguments in favor of the chosen conditional specifications. The parsimony and the empirical results below explain why we have not included an additional firm characteristic such as the size of firm $i$. As additional specifications, we consider the lagged default spread, term spread, monthly 30-day T-bill, aggregate consumption-to-wealth ratio (Lettau and Ludvigson (2001)), and labour-to-consumption ratio (Santos and Veronesi (2006)) as common instruments.

The CRSP database provides the monthly stock returns data and we exclude financial firms (Standard Industrial Classification Codes between 6000 and 6999) as in Fama and French (2008). The dataset after matching CRSP and Compustat contents comprises $n = 10,442$ stocks, and covers the period from January 1968 to December 2011 with $T = 546$ months. We constructed the quarterly stock returns from the monthly data and $T = 176$. In order to account for the unbalanced characteristic, if the monthly observability indicators $I_{i,t}$, $I_{i,t+1}$ and $I_{i,t+2}$ are observed, we built the returns of the quarter $s = 1, 2, 3, 4$ as the average of the three monthly returns at time $t$, $t + 1$ and $t + 2$. Otherwise, the observability indicator of the quarter
6.2 Results for financial models

In this section, we compute the diagnostic criteria for the linear factor models listed in Table 1. We fix \( \chi_{1,T} = 15 \) as advocated by Greene (2008) and \( \chi_{2,T} = 546/60 \), i.e., at least 60 months of return observations as in Bai and Ng (2002). In Table 3, we report the trimmed cross-sectional dimension \( n^\chi \). In some time-varying specifications, we face severe multicollinearity problems due to the correlations within the vector of regressors \( x_{i,t} \), that involves cross-products of factors \( f_t \) and instruments \( Z_{t-1} \). These problems explain why we shrink from \( n^\chi = 6,775 \) for time-invariant models to around three thousand assets for time-varying models. Table 4 reports the contribution in percentage of the first eigenvalue \( \mu_1 \) with respect to the variance of normalized residuals \( \frac{1}{n^\chi T} \sum_i 1^\chi \bar{\varepsilon}_i \bar{\varepsilon}_i' \), that is equal to one by construction under our variance scaling to one for each time series of residuals. We also report the number of omitted factors \( k \), the contribution of the first \( k \) eigenvalues, i.e., \( \sum_{j=1}^k \mu_j \), and the incremental contribution of the \( (k+1) \)-th eigenvalue \( \mu_{k+1} \). For each model, we also specify the numerical value of the penalisation function \( g \left( n^\chi, T \right) \), as defined in Section 5.

Let us start with the results for the time-invariant specifications. The number \( k \) of omitted factors is larger than one for the most popular financial models, e.g., the CAPM (Sharpe (1964)), the three-factor Fama-French model (FF) and the four-factor Carhart (1997) model (CAR). On the contrary, for the recent proposals based on profitability and investment (5FF, HXZ), quality minus junk (QMJ), and bet against beta (BAB) factors, we find no omitted latent factor. We observe that adding observable factors helps to reduce the contribution of the first eigenvalue \( \mu_1 \) to the variance of residuals. However, when we face latent factors, the omitted systematic contribution \( \sum_{j=1}^k \mu_j \) only accounts for a small proportion of the residual variance. For instance, we find \( k = 2 \) omitted factors in the CAPM. Those two latent factors only contribute to \( \mu_1 + \mu_2 = 4.06\% \) of the residual variance. Figure 1 summarizes this information graphically by displaying the penalized scree plots and the plots of cumulated eigenvalues for the CAPM. For instance, \( \mu_3 = 1.47\% \) lies below the horizontal line \( g(n^\chi, T) = 1.50\% \) in Panel A for the time-invariant CAPM, so that \( k = 2 \). In Panel B for the time-invariant CAPM, the vertical bar \( \mu_1 + \mu_2 = 4.06\% \) is divided into the contribution of
\( \mu_1 = 2.16\% \) (light grey area) and that of \( \mu_2 = 1.90\% \) (dark grey area). Figure 2 Panel A displays the scree plots of squared eigenvalues for the CAPM and the square \( g^2 (n^X, T) \) of the penalisation function relative to the squared Frobenius norm \( \sum_{t=1}^{T} \mu_t^2 \left( \frac{1}{nT} \sum_i 1_{i \in \mathbb{E}} \bar{x}_i' \bar{e}_i \right) \). By construction, the conclusion of the number of omitted factor is the same as for the scree plot shown in Figure 1. From the plot of cumulated squared eigenvalues in Figure 2 Panel B, we conclude that the two omitted factors contribute more to the relative explanation of the correlation part than of the residual variance. For example, we get that the sum of the square of the two first eigenvalues accounts for \( 22.51\% \) of the square of the Frobenius norm for the time-invariant CAPM. Thus, the two latent factors are much more representative of the off-diagonal components.

We conclude similarly for the time-invariant FF model, even if the correlation explanation provided by the single omitted factor is lower.

For the time-varying specifications (i) and (ii) of Table 4, we still find one omitted factor for the CAPM. The scaled three-factor FF model with \( Z_{t-1} = (1, divY_{t-1})' \) passes the diagnostic criterion. The largest eigenvalue \( \mu_1 = 1.37\% \) lies below the level \( g(n^X, T) = 2.05\% \) and its square \( \mu_1^2 \) only contributes to \( 5.80\% \) of the square of the Frobenius norm, so that \( k = 0 \). The additional stock specific instrument \( Z_{i,t-1} = bm_{i,t-1} \) is not necessary to exhaust the cross-sectional dependence. Hence, the empirical message of Table 4 is that we can choose either among time-invariant specifications with at least four financial factors, or a scaled FF model if we are only concerned by finding a specification with weak cross-sectional correlation. As already discussed in the introduction, this diagnostic step is crucial to decide whether we can feel comfortable with the chosen set of observable factors before proceeding further in an empirical analysis of a large cross sectional equity data set under the APT setting. Typical next steps are estimation of risk premia or tests of no arbitrage restrictions and factor tradability as in GOS to search for suitable empirical asset pricing models. The time-varying specification is more parsimonious for the factor space in the conditional sense \( (K = 3 \text{ versus } K = 4) \), but less parsimonious for the parameter space \( (d = 9 \text{ versus } d = 5) \). From an econometric point of view, it is not clear which parsimony we should favor to decide between the time-invariant specification (more factors, less parameters) and the time-varying specification (less factors, more parameters). For investment purposes, the first one is better suited for static (unconditional) decisions while the second one is better suited for dynamic (conditional) decisions. The choice between the two models should meet the investor needs or answer the empirical research question at hand. For a balanced panel...
of monthly returns for 4,883 stocks on the period January 1994 to December 1998 ($T = 60$), Bai and Ng (2002) find only two latent factors. As observed in GOS, measures of limits-to-arbitrage and missing factor impact (not reported here) like those in Pontiff (2006), Ang et al. (2009), Lam and Wei (2011), Stambaugh et al. (2015) decrease with the number of observable factors.

Concerning the additional factors and instruments mentioned in Section 6.1, none of them allows to reach a more parsimonious factor structure in a time-invariant or time-varying setting. Moreover, neither the time-invariant CAPM, FF and CAR models, nor their time-varying specifications with term spread, default spread, and book-to-market equity used in GOS, pass the diagnostic criterion. As conjectured in GOS, this might be one reason for the rejection of the asset pricing restrictions.

### 6.3 Results for macroeconomic models

In this section, we perform the empirical exercises on the macroeconomic linear factor models listed in Table 2. We fix $\chi_{1,T} = 15$ and $\chi_{2,T} = 176/20$, i.e., at least 20 quarterly return observations. In Table 5, we report the trimmed cross-sectional dimension $n^x$. The quarterly dataset has 6,707 stocks with more than twenty quarterly observations. The trimming is driven by the multicollinearity between regressors, when $n^x < 6,707$. Table 5 further reports the empirical results for the macroeconomic models. The time-invariant specifications which include only macroeconomic variables (CCAPM, NDC and DC, LVX, and CRR) and exclude the market, do not pass the diagnostic criterion. We find $k = 1$ omitted factors. Moreover, $\mu_1$ is about 8% of the residual variance in Table 5 and $\mu_1^2$ accounts for 37% of the square of the Frobenius norm, in contrast to the 4.06% and 22.51% found for the time-invariant CAPM with monthly returns. The latent factors in the macroeconomic models are both representative of the residual variance (diagonal values) and the correlation part (off-diagonal values). When we incorporate the market (EZ and YO), we find no omitted latent factors. This is not surprising since, for quarterly data, the CAPM already achieves a specification with weak cross-sectional correlation, with $\mu_1 = 3.15\%$, $g(n^x, T) = 3.74\%$, and $n^x = 6,707$. We do not report results for time-varying specifications. We have a limited sample size $T = 176$. Because of multicollinearity problems and the parameter dimension being up to $d = 14$, the estimation yields imprecise results. The trimmed sample size $n^x$ is often lower than $T$, which casts doubt about empirical results obtained under a large panel assumption.

### Table 1: Financial linear factor models

| Model     | Factors                                      | K |
|-----------|----------------------------------------------|---|
| CAPM      | $r_{m,t}$                                   | 1 |
| FF        | $r_{m,t}, r_{smb,t}, r_{hml,t}$              | 3 |
| CAR       | $r_{m,t}, r_{smb,t}, r_{hml,t}, r_{mom,t}$   | 4 |
| 5FF       | $r_{m,t}, r_{smb,t}, r_{hml,t}, r_{rmw,t}, r_{cma,t}$ | 5 |
| HXZ       | $r_{m,t}, r_{me,t}, r_{i/a,t}, r_{roeq,t}$   | 4 |
| FF and QMJ| $r_{m,t}, r_{smb,t}, r_{hml,t}, qmj_t$       | 4 |
| FF and BAB| $r_{m,t}, r_{smb,t}, r_{hml,t}, bab_t$       | 4 |

The table lists the linear factor models based on financial variables. We estimate these specifications by using monthly data. For each model, we report the factors labeling and their number $K$. FF, CAR, 5FF, HXZ, QMJ and BAB refer to the three Fama-French factors, the four Carhart factors, the five Fama-French factors, the four Hou-Xue-Zhang factors, quality minus junk factor, and bet against beta factor.

### Table 2: Macroeconomic linear factor models

| Model     | Factors                                      | K |
|-----------|----------------------------------------------|---|
| CCAPM     | $cg_t$                                       | 1 |
| EZ        | $r_{m,t}, cg_t$                             | 2 |
| NDC and DC| $ndeg_t, dcg_t$                             | 2 |
| YO        | $r_{m,t}, ndeg_t, dcg_t$                     | 3 |
| LVX       | $dh_t, dcorpt, dncorp_t$                     | 3 |
| CRR       | $mp_t, ui_t, dei_t, uts_t, upr_t$            | 5 |

The table lists the linear factor models based on macroeconomic variables and the market. We estimate these specifications by using quarterly data. For each model, we report the factors labeling and their number $K$. EZ, NDC and DC, YO, LVX and CRR refer to the two Epstein-Zin factors, the two nondurable and durable consumption growth factors, the three Yogo factors, the three Li-Vassalou-Xing factors, and the five Chen-Roll-Ross factors.
Table 3: Trimmed cross-sectional dimensions $n^x$ and number $d$ of parameters to estimate for financial models

| Financial model | Time-invariant | Time-varying |
|----------------|----------------|--------------|
|                | $n^x$          | (i) $d$ $n^x$ | (ii) $d$ $n^x$ |
| CAPM           | 6,775          | 5 3,766      | 8 3,004       |
| FF             | 6,775          | 9 3,536      | 14 2,780      |
| CAR            | 6,775          | 11 3,468     | 17 2,608      |
| 5 FF           | 6,775          | 13 2,957     | 20 1,991      |
| HXZ            | 6,775          | 11 3,344     | 17 2,612      |
| FF and QMJ     | 6,775          | 11 3,365     | 17 2,423      |
| FF and BAB     | 6,775          | 11 3,224     | 17 2,441      |

For each financial model of Table 1, we report the trimmed cross-sectional dimension $n^x$ for estimation from monthly data. For the time-varying specifications, we give the dimension $d$ of vector $x_{i,t}$ and $n^x$ for two sets of instruments: (i) $Z_{t-1} = (1, \text{div}Y_{t-1})'$ and (ii) $Z_{t-1} = (1, \text{div}Y_{t-1})'$, $Z_{i,t-1} = bm_{i,t-1}$. For the time-invariant specifications, we have $d = K + 1$ (see Table 1).
Table 4: Results for time-invariant and time-varying financial models

| Financial model | Panel A - Time-invariant | Panel B - Time-varying |
|-----------------|--------------------------|------------------------|
|                 | $\mu_1$ | $k$ | $\sum_{j=1}^{k} \mu_j$ | $\mu_{k+1}$ | penalty | $\mu_1$ | $k$ | $\sum_{j=1}^{k} \mu_j$ | $\mu_{k+1}$ | penalty |
| CAPM            | 2.16% | 2 | 4.06% | 1.47% | 1.50% | (i) 2.87% | 1 | 2.87% | 1.79% | 1.82% |
|                 | (ii) | | | | | 3.00% | 1 | 3.00% | 1.98% | 2.00% |
| FF              | 2.03% | 1 | 2.03% | 1.16% | 1.18% | (i) 1.37% | 0 | 0.00% | 1.37% | 2.05% |
|                 | (ii) | | | | | 1.53% | 0 | 0.00% | 1.53% | 2.17% |

|                 | (ii) | | | | | 1.54% | 0 | 0.00% | 1.54% | 2.20% |
| FF and QMJ      | 1.39% | 0 | 0.00% | 1.39% | 1.79% | (i) 1.33% | 0 | 0.00% | 1.33% | 2.07% |
|                 | (ii) | | | | | 1.60% | 0 | 0.00% | 1.60% | 2.24% |
| FF and BAB      | 1.64% | 0 | 0.00% | 1.64% | 1.79% | (i) 1.40% | 0 | 0.00% | 1.40% | 2.09% |
|                 | (ii) | | | | | 1.58% | 0 | 0.00% | 1.58% | 2.24% |

The table shows the contribution of the first eigenvalue $\mu_1$ to the variance of normalised residuals, the number of omitted factors $k$, the contributions of the first $k$, and of the $(k+1)$-th eigenvalues, and the penalty term. Panels A and B report results for time-invariant and time-varying financial models estimated from monthly data, respectively. The time-varying specifications use two sets of instruments: (i) $Z_{t-1} = (1, divY_{t-1})'$ and (ii) $Z_{t-1} = (1, divY_{t-1})'$, $Z_{i,t-1} = bm_{i,t-1}$.

For each macroeconomic model of Table 2, we report the trimmed cross-sectional dimension $n^\chi$ for time-invariant specifications estimated from quarterly data. We further show the contribution of the first eigenvalue $\mu_1$ to the variance of normalised residuals, the number of omitted factors $k$, the contributions of the first $k$, and of the $(k + 1)$-th eigenvalues, and the penalty term.

| Macroeconomic model | $n^\chi$ | $\mu_1$ | $k$ | $\sum_{j} \mu_j$ | $\mu_{k+1}$ | penalty |
|---------------------|----------|---------|-----|------------------|--------------|---------|
| CCAPM               | 6,707    | 8.12%   | 1   | 8.12%            | 6.24%        | 6.28%   |
| EZ                  | 6,707    | 3.07%   | 0   | 0.00%            | 3.07%        | 3.74%   |
| NDC and DC          | 6,306    | 8.07%   | 1   | 8.06%            | 6.14%        | 6.17%   |
| YO                  | 6,270    | 3.38%   | 0   | 0.00%            | 3.38%        | 3.76%   |
| LVX                 | 6,707    | 7.96%   | 1   | 7.96%            | 6.09%        | 6.13%   |
| CRR                 | 6,153    | 6.42%   | 2   | 11.30%           | 2.45%        | 2.48%   |
Panel A plots the scree-plot of the values of the first five eigenvalues in percentage, i.e., $\mu_j \left( \frac{1}{nT} \sum_i 1^X_i \hat{\varepsilon}_i \right)$ with $j = 1, \ldots, 5$. The horizontal line corresponds to the penalty function. Panel B plots the cumulated eigenvalues in percentage. The light grey area corresponds to $\sum_{l=1}^{j-1} \mu_l \left( \frac{1}{nT} \sum_i 1^X_i \hat{\varepsilon}_i \right)$, the dark grey is the contribution of the $j$th eigenvalue in percentage. The figure reports results for the CAPM for the time-invariant and time-varying specifications with $Z_{t-1} = (1, \text{div}Y_{t-1})'$. 

Electronic copy available at: https://ssrn.com/abstract=2817458
Panel A plots the scree-plot of the values of the first five squared eigenvalues in percentage, i.e.,

\[
\mu_j^2 \left( \frac{1}{n^x T} \sum_i 1_i^x \bar{\varepsilon}_t \bar{\varepsilon}_t' \right) / \sum_{l=1}^{T} \mu_l^2 \left( \frac{1}{n^T} \sum_i 1_i^l \bar{\varepsilon}_t \bar{\varepsilon}_t' \right) \text{ with } j = 1, \ldots, 5. \]

The horizontal line corresponds to the penalty function \( g(n^x, T)^2 / \sum_{l=1}^{T} \mu_l^2 \left( \frac{1}{n^T} \sum_i 1_i^l \bar{\varepsilon}_t \bar{\varepsilon}_t' \right) \). Panel B plots the cumulated squared eigenvalues in percentage.

The light grey area corresponds to \( \sum_{l=1}^{j-1} \mu_l^2 \left( \frac{1}{n^x T} \sum_i 1_i^x \bar{\varepsilon}_t \bar{\varepsilon}_t' \right) / \sum_{l=1}^{T} \mu_l^2 \left( \frac{1}{n^T} \sum_i 1_i^l \bar{\varepsilon}_t \bar{\varepsilon}_t' \right) \), the dark grey is the contribution of the \( j \)th squared eigenvalue in percentage. The figure reports results for the CAPM for the time-invariant and time-varying specifications with \( Z_{t-1} = (1, \text{div} Y_{t-1})' \).
Appendix 1 Regularity conditions

In this appendix, we list and comment additional assumptions used in the proofs in Appendix 2. The error terms \( (\varepsilon_{i,t}) \) are \( \varepsilon_{i,t} = u_{i,t} \) under model \( M_1 \), and \( \varepsilon_{i,t} = \theta_i h_t + u_{i,t} \) under model \( M_2 \) (see Equation (5)). Since models \( M_1 (k) \) and \( M_2 (k) \) are subsets of model \( M_2 \), the assumptions stated for \( M_2 \) also hold for \( M_1 (k) \) and \( M_2 (k) \), for any \( k \geq 1 \). We use \( M \) as a generic constant in the assumptions.

Assumption A.1 For a constant \( M > 0 \) and for all \( n, T \in \mathbb{N} \), we have:

\[
\frac{1}{n^2 T^2} \sum_{i,j} \sum_{t_1,t_2,t_3,t_4} E \left[ \left| E \left[ u_{i,t_1} u_{i,t_2} u_{j,t_3} u_{j,t_4} \mid x_{i,T}, x_{j,T}, \gamma_i, \gamma_j \right] \right] \right] \leq M.
\]

Assumption A.2 We have \( E[|u_{i,t}|] \leq M \), for all \( i, t \), and some constants \( q \geq 8 \) and \( M > 0 \).

Assumption A.3 Let \( \delta = \delta_n \uparrow \infty \) be a diverging sequence such that \( \sqrt{T}/\delta^{q-1} = o(1) \) and \( \delta \geq n^\beta \), for \( \beta > 2/q \). Let \( u_{i,t} = u_{i,t} 1\{|u_{i,t}| \leq \delta\} - E[u_{i,t} 1\{|u_{i,t}| \leq \delta\}] \gamma_i \). Then:

\[
\frac{1}{n^k} \sum_{i_1,\ldots,i_k} \sum_{t_1,\ldots,t_k} E \left[ \left| E\left[ e_{i_1,t_1} e_{i_2,t_2} e_{i_3,t_3} \cdots e_{i_{k-1},t_{k-1}} e_{i_k,t_k} \gamma_{i_1}, \ldots, \gamma_{i_k}\right] \right] \right] \leq M^k,
\]

for a sequence of integers \( k = k_n \uparrow \infty \) and a constant \( M > 0 \), where indices \( i_1, \ldots, i_k \) run from \( 1 \) to \( n \), and indices \( t_1, \ldots, t_k \) from \( 1 \) to \( T \).

Assumption A.4 There exists a constant \( M > 0 \) such that \( \|x_{i,t}\| \leq M \), P-a.s., for any \( i \) and \( t \).

Assumption A.5 Under model \( M_2 \), a) there exists a constant \( M > 0 \) such that \( \|h_t\| \leq M \), P-a.s., for all \( t \). Moreover, b) \( \|\theta_i\| < M \), for all \( i \).

Assumption A.6 Under model \( M_2 \), for a constant \( M > 0 \) and for all \( n, T \in \mathbb{N} \), we have:

\[
\frac{1}{n^2 T^2} \sum_{i,j} \sum_{t_1,t_2,t_3,t_4} E \left[ \left| E\left[ (x_{i,t_1} h_{t_1}')(x_{i,t_2} h_{t_2}')(x_{j,t_3} h_{t_3}')(x_{j,t_4} h_{t_4}') \mid \gamma_i, \gamma_j\right] \right] \right] \leq M.
\]

Assumption A.7 The processes \( (I_t(\gamma)) \) and \( (\varepsilon_t(\gamma)) \) are independent.

Assumption A.8 There exist constants \( \eta, \bar{\eta} \in (0,1] \) and \( C_1, C_2, C_3, C_4 > 0 \) such that, for all \( \delta > 0 \) and \( n, T \in \mathbb{N} \), we have:
\[ P \left( \left\| \frac{1}{T} \sum_{t} I_{i,t} \left( h_{i,t} - \Sigma h \right) \right\| \geq \delta |\gamma_i| \right) \leq C_1 T \exp\{-C_2 \delta^2 T \eta \} + C_3 \delta^{-1} \exp\{-C_4 T \bar{\eta} \}. \]

Furthermore the same upper bound holds for

\[ P \left( \left| \frac{1}{T} \sum_{t} I_{i,t} - \mathbb{E}[I_{i,t} | \gamma_i] \right| \geq \delta |\gamma_i| \right), \]

\[ P \left( \left| \frac{1}{T} \sum_{t} (x_{i,t} x_{i,t}' - \mathbb{E}[x_{i,t} x_{i,t}' | \gamma_i]) \right| \geq \delta |\gamma_i| \right). \]

Assumption A.9 \( \inf_{1 \leq i \leq n} \mathbb{E}[I_{i,t} | \gamma_i] \geq M^{-1}, \) for all \( n \in \mathbb{N} \) and a constant \( M > 0. \)

Assumption A.10 The trimming constants \( \chi_{1,T} \) and \( \chi_{2,T} \) are such that \( \chi_{1,T} \chi_{2,T} = o(T g(n, T)). \)

Assumption A.11 We have \( \mu_1(W) = O_p(C_{n,T}^{-2}), \) where \( W = [w_{t,s}] \) is the \( T \times T \) matrix with elements

\[ w_{t,s} = \frac{1}{nT} \sum_{i} (I_{i,t} - \bar{I}_{t})(I_{i,s} - \bar{I}_{s}), \]

and \( \bar{I}_{t} = \frac{1}{n} \sum_{i} I_{i,t}. \)

Assumption A.1 restricts serial dependence in the bivariate process of error terms \((u_{i,t}, u_{j,t})\) of any two assets. It involves conditional expectations of products of error terms \(u_{i,t}\) for different dates and any pair of assets. That assumption can be satisfied under weak serial dependence of the errors \((u_{i,t}, u_{j,t})\), such as mixing, with mixing size uniformly bounded across pairs \((i, j)\). Assumption A.2 is an upper bound on higher-orders moments of \(u_{i,t}\) to control tail thickness. Assumption A.3 is a restriction on both serial and cross-sectional dependence of the error terms and on the growth rates of \(n\) and \(T\). We use Assumptions A.2 and A.3 to characterize the asymptotic behavior of the spectrum of the cross-sectional variance-covariance matrix of errors under the rival models. Assumption A.2 yields the so-called truncation and centralization lemmas, which are used together with Assumption A.3 in the proof of Lemma 1 building on Geman (1980), Yin et al. (1988) and Bai and Yin (1993). For those lemmas, we do not need a structure on the error terms based on matrix transformations of i.i.d. random variables as in Onatski (2010) and Ahn and Horenstein (2013). In Appendix 3, we show that Assumptions A.1 and A.3 are satisfied under cross-sectional block-dependence and time-series independence of the errors, provided \(n\) grows sufficiently faster than \(T\), i.e., the coefficient \( \gamma \) in Assumption 3 is such that \( \gamma \in (0, \gamma^*) \), with \( \gamma^* < 1 \) being a function of cross-sectional dependence and heavy tails of errors which we characterize explicitly in Lemma 7. Under cross-sectional independence of the errors, the condition \( T/n = o(1) \) is enough as discussed at the end of Appendix 3. The arguments in Yin et al. (1988), page 520, show that Assumption A.3 is also satisfied under i.i.d. \( u_{i,t} \).
and proportional asymptotics. Assumptions A.4 and A.5 require upper bounds on regressor values, latent factors and factor loadings. Assumption A.6 restricts serial dependence of the products of latent factors and regressors. Recall that matrices $x_{i,t}h_i'$ are zero-mean under Assumption 2. In Assumption A.7, we assume a missing-at-random design (Rubin (1976)), that is, independence between unobservability and return generation. Another design would require an explicit modeling of the link between the unobservability mechanism and the return process of the continuum of assets (Heckman (1979)); this would yield a nonlinear factor structure. Assumption A.8 a) restricts the serial dependence of the latent factors and the individual processes of observability indicators. Specifically, Assumption A.8 a) gives an upper bound for large deviation probabilities of the sample average of zero-mean random matrices $h_t h_i' - \Sigma_h$, computed over date with available observations for assets $i$, uniformly w.r.t. asset $i$. It implies that the unbalanced sample moment of squared components of the latent factor vector converges in probability to the corresponding population moment at a rate $O_p(T^{-n/2}(\log T)^c)$, for some $c > 0$. Assumptions A.8 b) and c) give similar upper bounds for large-deviation probabilities of sample averages of observability indicators and cross-moments of regressors uniformly w.r.t. asset $i$. We use such assumptions to get the convergence of time-series averages uniformly across assets as in GOS. Assumption A.9 implies that asymptotically the fraction of the time period in which an asset return is observed is bounded away from zero uniformly across assets, so that $\tau_i = \text{plim}_{T \to \infty} \tau_{i,T} = E[I_{i,t}\mid \gamma_{i}]^{-1}$ is bounded uniformly across all assets as in GOS. Assumption A.10 gives an upper bound on the divergence rate of the trimming constants. Assumption A.11 controls the rate at which the largest eigenvalue of the matrix with entries made of cross-sectional empirical covariances of observability indicators vanishes to zero. The matrix gathering those empirical covariances should not be associated to an omitted factor structure.
ONLINE SUPPLEMENTARY MATERIALS

A diagnostic criterion for approximate factor structure

Patrick Gagliardini, Elisa Ossola and Olivier Scaillet

These online supplementary materials provide the proofs of Propositions 1 to 3 (Appendix 2), the checks of Assumptions A.1 and A.3 under block dependence (Appendix 3), the proofs of technical Lemmas 1-11 (Appendix 4), and the verification that conditional independence implies Assumption 2 (Appendix 5).

Appendix 2 Proofs

We start by listing several results known from matrix theory. They are used several times in the proofs.

(i) Weyl inequality: The singular-value version states that if $A$ and $B$ are $T \times n$ matrices, then $\mu_{i+j-1}[(A + B)(A + B)']^{1/2} \leq \mu_i(AA')^{1/2} + \mu_j(BB')^{1/2}$, for any $1 \leq i, j \leq \min\{n, T\}$ such that $1 \leq i+j \leq \min\{n, T\} + 1$ (see Theorem 3.3.16 of Horn and Johnson (1985)). The Weyl inequality for $i = k + 1$ and $j = 1$ yields:

$$\mu_{k+1}[(A + B)(A + B)']^{1/2} \leq \mu_k(AA')^{1/2} + \mu_1(BB')^{1/2}, \quad (10)$$

$$\mu_{k+1}[(A + B)(A + B)']^{1/2} \geq \mu_{k+1}(AA')^{1/2} - \mu_1(BB')^{1/2}, \quad (11)$$

for any $T \times n$ matrices $A$ and $B$ and integer $k$ such that $0 \leq k \leq \min\{n, T\} - 1$. We also use Weyl inequality for eigenvalues: for any $T \times T$ symmetric matrices $A$ and $B$ we have $\mu_{i+j-1}(A + B) \leq \mu_i(A) + \mu_j(B)$, for any $1 \leq i, j \leq T$ such that $i + j \leq T + 1$ (see Theorem 8.4.11 in Bernstein (2009)).

(ii) Equality between largest eigenvalue and operator norm: The largest eigenvalue $\mu_1(A)$ of a symmetric positive semi-definite matrix $A$ is equal to its operator norm $\|A\|_{op} = \max_{x: \|x\| = 1} \|Ax\|$. Besides, $\|A\|_{op} \leq \|A\|$ for any square matrix $A$, where $\| : \|$ is the Frobenius norm (see e.g. Meyer (2000)).

(iii) Inequalities for the eigenvalues of matrix products: If $A$ and $B$ are $m \times m$ positive semidefinite and positive definite matrices, respectively,

$$\mu_k(A) \mu_m(B) \leq \mu_k(AB) \leq \mu_k(A) \mu_1(B), \quad (12)$$

for $k = 1, 2, ..., m$ (see Fact 8.19.17 in Bernstein (2009)).
(iv) Courant-Fischer min-max Theorem: If \( A \) is a \( T \times T \) symmetric matrix, we have, for \( k = 1, \ldots, T \),

\[
\mu_k(A) = \min_{G, \dim(G) = T-k+1} \max_{x \in G : \|x\| = 1} x' Ax,
\]

where the minimization is w.r.t. the \((T - k + 1)\)-dimensional linear subspace \( G \) of \( \mathbb{R}^T \) (see e.g. Bernstein (2009)). The max-min formulation states:

\[
\mu_k(A) = \max_{G, \dim(G) = k} \min_{x \in G : \|x\| = 1} x' Ax,
\]

where the maximization is w.r.t. the \( k \)-dimensional linear subspace \( G \) of \( \mathbb{R}^T \).

(vi) Courant-Fischer formula: If \( A \) is a \( T \times T \) symmetric matrix, we have, for \( k = 1, \ldots, T \),

\[
\mu_k(A) = \max_{x \in F_{k-1} : \|x\| = 1} x' Ax,
\]

where \( F_k \) is the orthogonal complement of \( F_{k-1} \), with \( F_k \) being the linear space spanned by the eigenvectors associated to the \( k \) largest eigenvalues of matrix \( A \), and \( F_0 \equiv \mathbb{R}^T \).

A.2.1 Proof of Proposition 1

a) The OLS estimator of \( \beta_i \) in matrix notation is \( \hat{\beta}_i = \left( \hat{X}_i' \hat{X}_i \right)^{-1} \hat{X}_i' \hat{R}_i \), with \( \hat{X}_i = X_i \odot X_i \) and \( \hat{R}_i = I_i \odot R_i \), where \( I_i \) is the \( T \times 1 \) vector of indicators \( I_{i,t} \) for asset \( i \), and \( \odot \) is the Hadamard product. We get the vector of residuals \( \hat{e}_i = R_i - X_i \left( \hat{X}_i' \hat{X}_i \right)^{-1} \hat{X}_i' \hat{R}_i \). Then, we have \( \tilde{e}_i = I_i \odot \hat{e}_i = M_{\hat{X}_i} \hat{R}_i = M_{\hat{X}_i} \hat{e}_i \), where \( \tilde{e}_i = I_i \odot e_i \) and \( M_{\hat{X}_i} = I_T - P_{\hat{X}_i} \), with \( P_{\hat{X}_i} = \hat{X}_i \left( \hat{X}_i' \hat{X}_i \right)^{-1} \hat{X}_i' \). Thus, under \( M_1 \), we have the decomposition \( 1_i^T \tilde{e}_i = \tilde{e}_i - (1 - 1_i^T)\tilde{e}_i - 1_i^T P_{\hat{X}_i} \tilde{e}_i \). From Weyl inequality (10) with \( k = 0 \), and the inequality between matrix norms, we get:

\[
\mu_1 \left( \frac{1}{nT} \sum_i 1_i^T \tilde{e}_i \tilde{e}_i' \right)^{1/2} \leq \mu_1 \left( \frac{1}{nT} \sum_i \tilde{e}_i \tilde{e}_i' \right)^{1/2} + I_1^{1/2} + I_2^{1/2},
\]

where:

\[
I_1 := \| \frac{1}{nT} \sum_i (1 - 1_i^T)\tilde{e}_i \tilde{e}_i' \|, \quad I_2 := \| \frac{1}{nT} \sum_i 1_i^T P_{\hat{X}_i} \tilde{e}_i \tilde{e}_i' P_{\hat{X}_i} \|.
\]

We bound the largest eigenvalue of matrix \( \frac{1}{nT} \sum_i \tilde{e}_i \tilde{e}_i' \) and the remainder terms \( I_1 \) and \( I_2 \) in the next two lemmas.
Lemma 1 Under model $\mathcal{M}_1$ and Assumptions 3, A.2, A.3, A.7, as $n, T \to \infty$, we have $\mu_1 \left( \frac{1}{nT} \sum_i \tilde{\varepsilon}_i \varepsilon_i' \right) = O_p(C_{n,T}^{-2})$.

Lemma 2 Under model $\mathcal{M}_1$ and Assumptions 3, A.1, A.2, A.4, A.8 b), c) and A.9, as $n, T \to \infty$, we have:

(i) $I_1 = O_p(T^{-b})$, for any $b > 0$; (ii) $I_2 = O_p(\chi_1 T \chi_2^2 T / T)$.

From Inequality (16) and Lemmas 1 and 2, we get $\xi = O_p(C_{n,T}^{-2}) + O_p(\chi_1 T \chi_2^2 T / T) - g(n, T)$. Then, from Assumption A.10 on the trimming constants, we get $\xi \geq C/2$, w.p.a. 1, and Proposition 1(b) follows.

b) Let us now consider the case $\mathcal{M}_2$. We have $\tilde{\varepsilon}_i = M_{\widetilde{X}_i} \tilde{\varepsilon}_i$ and $\tilde{\varepsilon}_i = \tilde{H}_i \theta_i + \tilde{u}_i$, where $\tilde{H}_i = I_i \odot H$ and $H$ is the $T \times m$ matrix of latent factor values, with $m \geq 1$. Hence, we have the decomposition $1_i \tilde{\varepsilon}_i = \tilde{H}_i \theta_i + \tilde{u}_i - (1 - 1_i^T) \tilde{\varepsilon}_i - 1_i X_i \tilde{H}_i \theta_i - 1_i P_{\widetilde{X}_i} \tilde{u}_i$. By using Weyl inequality (11) with $k = 0$, and the inequality between matrix norms, we get:

$$
\mu_1 \left( \frac{1}{nT} \sum_i 1_i \tilde{\varepsilon}_i \tilde{\varepsilon}_i' \right)^{1/2} \geq \mu_1 \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right)^{1/2} - \mu_1 \left( \frac{1}{nT} \sum_i \tilde{u}_i \tilde{u}_i' \right)^{1/2} - I^{1/2},
$$

(18)

where $I^{1/2} = I_1^{1/2} + I_3^{1/2} + I_4^{1/2}$, term $I_1$ is defined as in (17), and

$$
I_3^{1/2} := \| \frac{1}{nT} \sum_i \chi_i^2 P_{\tilde{X}_i} \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' P_{\tilde{X}_i} \|^{1/2},
$$

$$
I_4^{1/2} := \| \frac{1}{nT} \sum_i \chi_i^2 P_{\tilde{X}_i} \tilde{u}_i \tilde{u}_i' P_{\tilde{X}_i} \|^{1/2}.
$$

By Lemma 1 applied on $\tilde{u}_i$ instead of $\tilde{\varepsilon}_i$, we have $\mu_1 \left( \frac{1}{nT} \sum_i \tilde{u}_i \tilde{u}_i' \right) = O_p(C_{n,T}^{-2})$. Moreover, from the next Lemma 3 and Assumption A.10 on the trimming constants, we get $I = o_p(g(n, T))$ under $\mathcal{M}_2$.

Lemma 3 Under model $\mathcal{M}_2$ and Assumptions 3, A.2, A.4, A.5 and A.6, as $n, T \to \infty$, we have: (i) $I_1 = O_p(T^{-b})$, for any $b > 0$; (ii) $I_3 = O_p(\chi_1^4 T \chi_2^2 T / T)$; (iii) $I_4 = O_p(\chi_1^4 T \chi_2 T / T)$.

The next Lemma 4 provides a lower bound for the first term in the r.h.s. of Inequality (18).

Lemma 4 Under model $\mathcal{M}_2$ and Assumptions 1, A.8 and A.9, we have $\mu_1 \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right) \geq C$, w.p.a. 1, for a constant $C > 0$.

Then, from Inequality (18) and Lemma 4, we get $\xi \geq C/2$, w.p.a. 1, and Proposition 1(b) follows.
A.2.2 Proof of Proposition 2

We prove Proposition 2 along similar lines as Proposition 1 by exploiting the Weyl inequalities (10) and (11) for a generic \( k \).

a) Let us first consider the case \( M_1(k) \). We have \( \tilde{\varepsilon}_i = M_X \tilde{\xi}_i \) and \( \tilde{\varepsilon}_i = \tilde{H}_i \theta_i + \tilde{u}_i \), where \( \tilde{H}_i = I_i \odot H \) and \( H \) is the \( T \times k \) matrix of latent factor values. Then, \( 1^X \tilde{\varepsilon}_i = \tilde{H}_i \theta_i + \tilde{u}_i - (1 - 1^X) \tilde{\varepsilon}_i - 1^X P_{X_i} \tilde{H}_i \theta_i - 1^X P_{X_i} \tilde{u}_i \).

From Weyl inequalities (10) and (11), and the inequality between matrix norms, we get:

\[
\mu_{k+1} \left( \frac{1}{nT} \sum_i 1^X \tilde{\varepsilon}_i \tilde{\varepsilon}_i' \right)^{1/2} \leq \mu_{k+1} \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right)^{1/2} + \mu_1 \left( \frac{1}{nT} \sum_i \tilde{u}_i \tilde{u}_i' \right)^{1/2} + I^{1/2},
\]

where \( I^{1/2} = I_1^{1/2} + I_3^{1/2} \) and terms \( I_1, I_3 \) and \( I_4 \) are defined as in the proof of Proposition 1. Since model \( M_1(k) \) is included in model \( M_2 \) for any \( k \geq 1 \), we get \( I = o_p(g(n, T)) \), from Lemma 3 and Assumption A.10 on the trimming constants. Moreover, \( \mu_1 \left( \frac{1}{nT} \sum_i \tilde{u}_i \tilde{u}_i' \right) = O_p(C_{n, T}^{-2}) \) by Lemma 1 with \( \tilde{u}_i \) replacing \( \tilde{\varepsilon}_i \). The first term in the r.h.s. of (19) is bounded by the next lemma.

**Lemma 5** Under model \( M_1(k) \) and Assumptions A.5 and A.11, we have

\[
\mu_{k+1} \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right) = O_p(C_{n, T}^{-2}).
\]

The bound in Lemma 5 would be trivial in the case \( \tilde{H}_i = H \), i.e., with a balanced panel, because in that case

\[
\mu_{k+1} \left( \frac{1}{nT} \sum_i H \theta_i \theta_i' H' \right) = 0 \text{ under } M_1(k).
\]

From Inequality (19) and Lemma 5, we get \( \xi = O_p(C_{n, T}^{-2}) + o_p(g(n, T)) - g(n, T) \). Then, by the properties of \( g(n, T) \), Proposition 2(a) follows.

b) Let us now consider the case \( M_2(k) \). We have \( \tilde{\varepsilon}_i = M_X \tilde{\xi}_i \) and \( \tilde{\varepsilon}_i = \tilde{H}_i \theta_i + \tilde{u}_i \), where \( \tilde{H}_i = I_i \odot H \) and \( H \) is the \( T \times m \) matrix of latent factor values, with \( m \geq k + 1 \). By similar arguments as in part a), using Weyl inequalities (10) and (11), and the inequality between matrix norms, we get:

\[
\mu_{k+1} \left( \frac{1}{nT} \sum_i 1^X \tilde{\varepsilon}_i \tilde{\varepsilon}_i' \right)^{1/2} \geq \mu_{k+1} \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right)^{1/2} - \mu_1 \left( \frac{1}{nT} \sum_i \tilde{u}_i \tilde{u}_i' \right)^{1/2} - I^{1/2}.
\]

As in part a) we have \( \mu_1 \left( \frac{1}{nT} \sum_i \tilde{u}_i \tilde{u}_i' \right) = O_p(C_{n, T}^{-2}) \) and \( I = o_p(g(n, T)) \).

**Lemma 6** Under model \( M_2(k) \) and Assumptions I(i), 4, A.8 and A.9, we have \( \mu_{k+1} \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right) \geq C, \text{w.p.a.} \ 1 \), for a constant \( C > 0 \).
Then, from Inequality (20) and Lemma 6, we get $\xi \geq C/2$, w.p.a. 1, and Proposition 2(b) follows.

A.2.3 Proof of Proposition 3

Let us define the events $A_k = \{\xi(k) \geq 0\}$, $k = 0, \ldots, k_0 - 1$, and $A_{k_0} = \{\xi(k_0) < 0\}$. We have $P[\hat{k} = k_0] = P[\{A_0 \cap A_1 \cap \ldots \cap A_{k_0-1}\} \cap A_{k_0}]$. For generic events $B$ and $C$, we have $P[B \cap C] = P[B] + P[C] - P[B \cup C]$, and we conclude that $P[B \cap C] \to 1$ if both $P[B]$ and $P[C]$ converge to 1 since $P[B \cup C] \geq P[B]$ and $P[B \cup C] \geq P[C]$. Applying repeatedly this argument to the probability $P[\{A_0 \cap A_1 \cap \ldots \cap A_{k_0-1}\} \cap A_{k_0}]$ yields $P[\hat{k} = k_0] \to 1$ since $P[A_k] \to 1$, $k = 0, \ldots, k_0 - 1$, and $P[A_{k_0}] \to 1$, under $\mathcal{M}_1(k_0)$ from Proposition 2.

Appendix 3 Check of Assumptions A.1 and A.3 under block dependence

In this appendix, we verify that the high-level Assumptions A.1 and A.3 on serial and cross-sectional dependences of error terms are satisfied under a block-dependence structure in a serially i.i.d. framework.

Assumption BD.1 The error terms $u_t(\gamma)$ are i.i.d. over time with $E[u_t(\gamma)] = 0$, for all $\gamma \in [0, 1]$. For any $n$, there exists a partition of the interval $[0, 1]$ into $b_n \leq n$ subintervals of approximate length $B_n = O(1/b_n)$, such that $u_t(\gamma)$ and $u_t(\gamma')$ are independent if $\gamma$ and $\gamma'$ belong to different subintervals, and $b_n^{-1} = O(n^{-\alpha})$ as $n \to \infty$, where $\alpha \in (0, 1]$.

Assumption BD.2 The error terms $(u_t(\gamma))$, the factors $(f_t)$, and the instruments $(Z_t, Z_t(\gamma)), \gamma \in [0, 1]$, are mutually independent.

The block-dependence structure as in Assumption BD.1 is satisfied for instance when there are unobserved industry-specific factors independent among industries and over time, as in Ang et al. (2010). In empirical applications, blocks can match industrial sectors. Then, the number $b_n$ of blocks amounts to a couple of dozens, and the number of assets $n$ amounts to a couple of thousands. There are approximately $nB_n$ assets in each block, when $n$ is large. In the asymptotic analysis, Assumption BD.1 requires that the number of independent blocks grows with $n$ fast enough. Within blocks, covariances do not need to vanish asymptotically.
Lemma 7 Under Assumptions A.2 and BD.1: (i) Assumption A.1 holds. (ii) Assumption A.3 holds if
\[ \alpha > \frac{4}{q}, \tag{21} \]
and \( n \geq T^{1/\gamma} \) with
\[ \gamma < \alpha - \frac{4}{q} =: \gamma^*. \tag{22} \]

The condition in (21) yields a trade-off between the strength of cross-sectional dependence (which is inversely related to parameter \( \alpha \)) and the existence of higher order moments of the error terms (via coefficient \( q \geq 8 \) defined in Assumption A.2). The condition (22) provides a restriction on the relative growth rate of the cross-sectional and time-series dimensions. The upper bound \( \gamma^* < 1 \) on parameter \( \gamma \) implies that \( n \) must grow sufficiently faster than \( T \). This upper bound involves both cross-sectional dependence (via \( \alpha \)) and heavy tails (via \( q \)) of error terms. We can have \( \gamma \) (arbitrarily) close to 1 from below, if cross-sectional dependence is sufficiently weak (i.e. \( \alpha \) close to 1) and the tails of the errors are sufficiently thin (i.e. \( q \) large). The proof of Lemma 7 shows that we can take \( \delta = n^\beta \) for any \( \beta \in \left( \frac{2}{q}, \frac{\alpha - \gamma^*}{2} \right) \) to match Assumption A.3.

Appendix 4 Proofs of technical Lemmas

A.4.1 Proof of Lemma 1

We prove:
\[ \limsup_{n,T \to \infty} \mu_1 \left( \frac{1}{n} \tilde{E} \tilde{E}' \right) \leq C, \text{ a.s.,} \tag{23} \]
for a constant \( C < \infty \), where \( \tilde{E} \) is the \( T \times n \) matrix with elements \( \tilde{e}_{i,t} = I_{i,t} \varepsilon_{i,t} \). Then, the statement of Lemma 1 follows. To show (23), we follow similar arguments as in Geman (1980), Yin et al. (1988), and Bai and Yin (1993).

We first establish suitable versions of the so-called truncation and centralization lemmas. We denote by \( \Xi \) and \( E \) the \( T \times n \) matrices with elements \( (\xi_{i,t}) \) and \( (e_{i,t}) \), where \( \xi_{i,t} = \varepsilon_{i,t} 1\{|\varepsilon_{i,t}| \leq \delta\} \) and \( e_{i,t} = \xi_{i,t} - E[|\xi_{i,t}| \gamma_i] \), and \( \delta = \delta_n \uparrow \infty \) is a diverging sequence as in Assumption A.3. Let us define matrices \( \tilde{E} \) and \( \tilde{\Xi} \) with elements \( (I_{i,t} \varepsilon_{i,t}) \) and \( (I_{i,t} \xi_{i,t}) \) by analogy to \( \tilde{E} \). Lemma 8 shows that we can substitute the truncated \( \xi_{i,t} \) and \( I_{i,t} \xi_{i,t} \) for \( \varepsilon_{i,t} \) and \( I_{i,t} \varepsilon_{i,t} \), and Lemma 9 shows that we can substitute the centered \( I_{i,t} \varepsilon_{i,t} \)
for the $I_{i,t} \xi_{i,t}$ to show boundedness of the largest eigenvalue in (23). We prove Lemma 8 and Lemma 9 in Sections A.4.8 and A.4.9 below.

**Lemma 8** Under Assumption A.2, if $\delta = \delta_n$ is such that $\delta \geq n^\beta$ for $\beta > 2/q$, then: (i) $P(\mathcal{E} \neq \Xi \text{ i.o.}) = 0$, and (ii) $P\left(\tilde{\mathcal{E}} \neq \tilde{\Xi} \text{ i.o.}\right) = 0$, where i.o. means infinitely often for $n = 1, 2, \ldots$.

**Lemma 9** Under Assumption A.2, if $\delta = \delta_n \uparrow \infty$ such that $\sqrt{T}/\delta^q = o(1)$, then:

$$\mu_1 \left(\frac{1}{n} \tilde{\Xi} \tilde{\Xi}'\right) = \mu_1 \left(\frac{1}{n} \tilde{E} \tilde{E}'\right) + o(1), \ a.s.$$

From Lemma 8(ii) and Lemma 9, condition (23) is implied by:

$$\limsup_{n,T \to \infty} \mu_1 \left(\frac{1}{n} \tilde{E} \tilde{E}'\right) \leq C, \ a.s., \quad (24)$$

for a constant $C < \infty$. Now, we use that the upper bound (24) is implied by the condition:

$$\sum_{n=1}^{\infty} E \left[\left(\mu_1 \left(\frac{1}{n} \tilde{E} \tilde{E}'\right) / C\right)^k\right] < \infty, \quad (25)$$

for an increasing sequence of integers $k = k_n \uparrow \infty$. To prove the validity of condition (25), we use that:

$$\mu_1 \left(\frac{1}{n} \tilde{E} \tilde{E}'\right)^k \leq T \mu \left(\left(\frac{1}{n} \tilde{E} \tilde{E}'\right)^k\right) = \frac{1}{n^k} \sum_{\gamma_1, \ldots, \gamma_k} \tilde{e}_{\gamma_1, t_k} \tilde{e}_{\gamma_1, t_k} \tilde{e}_{\gamma_2, t_2} \tilde{e}_{\gamma_2, t_2} \tilde{e}_{\gamma_3, t_2} \cdots \tilde{e}_{\gamma_{k-1}, t_{k-1}} \tilde{e}_{\gamma_{k-1}, t_{k-1}} \tilde{e}_{\gamma_k, t_k},$$

for any integer $k$, where in the summation the indices $i_1, \ldots, i_k$ run from 1 to $n$, and indices $t_1, \ldots, t_k$ run from 1 to $T$. Therefore, from Assumption A.7:

$$E \left[\mu_1 \left(\frac{1}{n} \tilde{E} \tilde{E}'\right)^k\right] \leq \frac{1}{n^k} \sum_{\gamma_1, \ldots, \gamma_k} E \left[\left(\sum_{\gamma_1, \ldots, \gamma_k} \tilde{e}_{\gamma_1, t_k} \tilde{e}_{\gamma_1, t_k} \tilde{e}_{\gamma_2, t_2} \tilde{e}_{\gamma_2, t_2} \tilde{e}_{\gamma_3, t_2} \cdots \tilde{e}_{\gamma_{k-1}, t_{k-1}} \tilde{e}_{\gamma_{k-1}, t_{k-1}} \tilde{e}_{\gamma_k, t_k} \right) / C\right].$$

Then, we get $E \left[\mu_1 \left(\frac{1}{n} \tilde{E} \tilde{E}'\right)^k\right] \leq M^k$, for the sequence $k = k_n$ defined in Assumption A.3. Condition (25) holds for any $C > M$, and the conclusion follows.

### A.4.2 Proof of Lemma 2

i) We have $I_i^2 = \| \frac{1}{nT} \sum_{i} (1 - 1_i^X) \xi_i \xi_i' \|^2 = \frac{1}{n^2 T^2} \sum_{i,j} (1 - 1_i^X)(1 - 1_j^X)(\xi_i' \xi_j)^2 = \frac{1}{n^2 T^2} \sum_{i,j} \sum_{t_1, t_2} (1 - 1_i^X)(1 - 1_j^X)I_{i,t_1}I_{j,t_1}I_{i,t_2}I_{j,t_2}I_{i,t_1} \xi_i \xi_i \xi_i \xi_i', \xi_j \xi_j \xi_j \xi_j$. By the Cauchy-Schwarz inequality:

$$E[I_i^2] \leq \frac{1}{n^2 T^2} \sum_{i,j} \sum_{t_1, t_2} E[1 - 1_i^X]^{1/4} E[1 - 1_j^X]^{1/4} E[\xi_i^{\delta_1}]^{1/8} E[\xi_j^{\delta_2}]^{1/8} E[\xi_i^{\delta_3}]^{1/8} E[\xi_j^{\delta_4}]^{1/8} E[\xi_i^{\delta_5}]^{1/8} E[\xi_j^{\delta_6}]^{1/8}. \quad \text{7}$$
Now, we have $E[\varepsilon_{8i,t}] \leq M$ from Assumption A.2 and $E[1 - 1^X_i] = P[1^X_i = 0] = O(T^{-\bar{b}})$ for any $\bar{b} > 0$, uniformly in $i$ and $t$ from Assumptions A.4, A.8c) and A.9 (see Lemma 7 in GOS). Then, $I_1 = O_p(T^{-\bar{b}})$ for any $\bar{b} > 0$.

ii) We have:

$$I_2^2 = \frac{1}{nT} \sum_i 1^X_i \|P_{X_i} \tilde{\varepsilon}_i \tilde{\varepsilon}_i^T P_{X_i}\|^2 = \frac{1}{n^2T^2} \sum_{i,j} 1^X_i \|\tilde{\varepsilon}_i \tilde{\varepsilon}_i^T P_{X_i} P_{X_j} \tilde{\varepsilon}_j \tilde{\varepsilon}_j^T P_{X_j}\|$$

$$= \frac{1}{n^2T^2} \sum_{i,j} 1^X_i \|\tilde{\varepsilon}_i \tilde{\varepsilon}_i^T P_{X_i} P_{X_j} \tilde{\varepsilon}_j \tilde{\varepsilon}_j^T P_{X_j}\|$$

$$= \frac{1}{n^2T^2} \sum_{i,j} 1^X_i \|\tilde{\varepsilon}_i \tilde{\varepsilon}_i^T P_{X_i} P_{X_j} \tilde{\varepsilon}_j \tilde{\varepsilon}_j^T P_{X_j}\|$$

$$= \frac{1}{n^2T^2} \sum_{i,j} 1^X_i \|\tilde{\varepsilon}_i \tilde{\varepsilon}_i^T P_{X_i} P_{X_j} \tilde{\varepsilon}_j \tilde{\varepsilon}_j^T P_{X_j}\|$$

where $\tilde{Q}_{x,i,j} = \frac{1}{T\bar{b}_{ij}} \sum_t I_{i,t}I_{j,t}x_{i,t}x_{j,t}$ and $\bar{b}_{ij} = T/T_{ij}$. By using $Tr(AB^T) \leq \|A\|\|B\|$, $1^X_i \|\tilde{Q}_{x,i}^{-1}\| \leq C\chi_{1,T}^2$, $1^X_i \|\tilde{Q}_{x,i}^{-1}\| \leq \chi_{2,T}$, $\|x_{i,t}\| \leq M$ (Assumption A.4), $\bar{b}_{ij} \geq 1$, for all $i$ and $t$, we get:

$$I_2^2 \leq \frac{C\chi_{1,T}^2 \chi_{2,T}^4}{n^2T^2} \sum_{i,j} 1^X_i \|\tilde{\varepsilon}_i \tilde{\varepsilon}_i^T P_{X_i} P_{X_j} \tilde{\varepsilon}_j \tilde{\varepsilon}_j^T P_{X_j}\|$$

Thus:

$$E[I_2^2|I_{i,t}, I_{j,t}, x_{i,t}, x_{j,t}, \gamma_i, \gamma_j] \leq \frac{C\chi_{1,T}^2 \chi_{2,T}^4}{n^2T^2} \sum_{i,j} 1^X_i \|\tilde{\varepsilon}_i \tilde{\varepsilon}_i^T P_{X_i} P_{X_j} \tilde{\varepsilon}_j \tilde{\varepsilon}_j^T P_{X_j}\|$$

$$\leq \frac{CM^2\chi_{1,T}^2 \chi_{2,T}^4}{n^2T^2} \sum_{i,j} 1^X_i \|\tilde{\varepsilon}_i \tilde{\varepsilon}_i^T P_{X_i} P_{X_j} \tilde{\varepsilon}_j \tilde{\varepsilon}_j^T P_{X_j}\|$$

Hence $E[I_2^2] \leq \frac{CM^2\chi_{1,T}^2 \chi_{2,T}^4}{n^2T^2}$, from Assumptions A.1 and A.4. It follows $E[I_2^2] = O(\frac{\chi_{1,T}^2 \chi_{2,T}^4}{T^2})$, which implies $I_2 = O_p(\frac{\chi_{1,T}^2 \chi_{2,T}^4}{T^2})$.

**A.4.3 Proof of Lemma 3**

i) The proof of Lemma 3(i) is the same as that of Lemma 2(i), since the bound $E[|\varepsilon_{i,t}|^8] \leq M$ applies under $\mathcal{M}_2$ as well (Assumptions A.2 and A.5).

ii) The proof of Lemma 3(ii) is similar to that of Lemma 2(ii), by replacing $\tilde{\varepsilon}_i$ with $\tilde{H}_i \theta_i$ and using
Assumption A.6. We have:
\[ I_2^2 = \left\| \frac{1}{nT} \sum_i \xi_i P_{X_i} \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' P_{X_i} \right\|^2 = \frac{1}{n^2T^2} \sum_{i,j} \xi_i \xi_j \left[ P_{X_i} \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' P_{X_j} \right] \]
\[ = \frac{1}{n^2T^2} \sum_{i,j} \xi_i \xi_j \frac{T_i^2}{T^2} \frac{T_j^2}{T^2} \left[ \tilde{X}_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \tilde{X}_j \right] \]  
By using \( Tr(AB') \leq \|A\|\|B\| \), \( 1^\alpha \frac{\|\hat{Q}_{x,i}^{-1}\|}{\|\frac{1}{T} \tilde{X}_i \tilde{H}_i \|} \leq C \chi_{1,T}^2, 1^\alpha \|\theta_i\| \leq \chi_{2,T}, \|x_{i,t}\| \leq M, \|x_{i,t}\| \leq M, \tau_{i,j,T} \geq 1 \), for all \( i \) and \( t \), we get:
\[ I_2^2 \leq \frac{C \chi_{1,T}^2 \chi_{2,T}^4}{n^2T^4} \sum_{i,j} \left\| \frac{\hat{H}_i \tilde{X}_i}{\sqrt{T}} \right\|^2 \left\| \frac{\tilde{H}_i' \tilde{X}_j}{\sqrt{T}} \right\|^2 \]
\[ = \frac{C \chi_{1,T}^2 \chi_{2,T}^4}{n^2T^4} \sum_{i,j} \sum_{t_1,t_2,t_3,t_4} I_{i,t_1} I_{j,t_2} I_{j,t_3} I_{j,t_4} h'_{t_1} h_{t_2} x'_{i,t_1} x_{i,t_2} h_{t_3} h_{t_4} x'_{j,t_3} x_{j,t_4}. \]
Thus:
\[ E[I_2^2|I_{T,i}, I_{T,j}, \gamma_i, \gamma_j] \leq \frac{C \chi_{1,T}^2 \chi_{2,T}^4}{n^2T^4} \sum_{i,j} \sum_{t_1,t_2,t_3,t_4} \left| E[h'_{t_1} h_{t_2} x'_{i,t_1} x_{i,t_2} h_{t_3} h_{t_4} x'_{j,t_3} x_{j,t_4} \| \gamma_i, \gamma_j] \right|. \]
Hence \( E[I_2^2] \leq \frac{CM \chi_{1,T}^2 \chi_{2,T}^4}{T^2}, \) from Assumption A.6. It follows \( E[I_2^2] = O(\frac{\chi_{1,T}^2 \chi_{2,T}^4}{T^2}) \), which implies \( I_2 = O_p(\frac{\chi_{1,T}^2 \chi_{2,T}^4}{T}) \).

iii) The proof of Lemma 3(iii) is the same as that of Lemma 2(ii), by replacing \( \tilde{e}_i \) with \( \tilde{u}_i \).

A.4.4 Proof of Lemma 4
We have \( \mu_1 \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right) = \max_{x \in \mathbb{R}^T: \|x\| = 1} x' \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right) x. \) From Assumption 1 (i), matrix \( \frac{1}{T} \tilde{H}' \tilde{H} = \frac{1}{T} \sum_i h_i h_i' \) is positive definite w.p.a. 1. Thus, for any \( a \in \mathbb{R}^m \) with \( \|a\| = 1 \), the vector...
\( x(a) \in \mathbb{R}^T \) defined by \( x(a) = \frac{1}{\sqrt{T}} H a [a' (H' H/T) a]^{-1/2} \) is such that \( \| x(a) \| = 1 \), w.p.a. 1. Therefore:

\[
\mu_1 \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_t \theta'_t \tilde{H}'_i \right) \geq \max_{a \in \mathbb{R}^m: \| a \| = 1} x(a)' \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_t \theta'_t \tilde{H}'_i \right) x(a)
\]

\[
= \max_{a \in \mathbb{R}^m: \| a \| = 1} \frac{a' \left[ \frac{1}{n} \sum_i \tilde{H}'_i (H' T) \theta_t \theta'_t (H' T) \right] a}{a' (H' H/T) a}
\]

\[
= \max_{a \in \mathbb{R}^m: \| a \| = 1} \frac{a' \left[ \frac{1}{n} \sum_i \tau_i^{-2} \left( \frac{1}{T} I_i \sum_t I_{i,t}h_t h'_t \right) \theta_t \theta'_t \left( \frac{1}{T} \sum_t I_{i,t}h_t h'_t \right) \right] a}{a' \left( \frac{1}{T} \sum_t h_t h'_t \right) a}
\]

We have \( a' \left( \frac{1}{T} \sum_t h_t h'_t \right) a \leq \mu_1 \left( \frac{1}{T} \sum_t h_t h'_t \right) \), for any \( a \in \mathbb{R}^m \) such that \( \| a \| = 1 \), and from Assumption 1 (i), we have \( \mu_1 \left( \frac{1}{T} \sum_t h_t h'_t \right) \leq 2 \mu_1 (\Sigma_h) \) w.p.a. 1. Moreover, from the proof of Lemma 3 in GOS, under Assumptions A.8 and A.9, and \( n = O\left( T^{1/2} \right) \), \( \gamma > 0 \), we have \( \sup_{1 \leq t \leq n} \left\| \frac{1}{T} \sum_t I_{i,t}h_t h'_t - \Sigma_h \right\| = o_p(1) \), \( \sup_{1 \leq t \leq n} |\tau_{i,T} - \tau_i| = o_p(1) \), and \( 1 \leq \tau_i \leq M \), for all \( i \). It follows:

\[
\mu_1 \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_t \theta'_t \tilde{H}'_i \right) \geq C \max_{a \in \mathbb{R}^m: \| a \| = 1} a' \Sigma_h \left( \frac{1}{n} \sum_i \theta_t \theta'_t \right) \Sigma_h a = C \mu_1 \left( \Sigma_h \left( \frac{1}{n} \sum_i \theta_t \theta'_t \right) \Sigma_h \right),
\]

w.p.a. 1, for a constant \( C > 0 \). From inequality (12) for the eigenvalues of a matrix product applied twice, we have \( \mu_1 \left( \Sigma_h \left( \frac{1}{n} \sum_i \theta_t \theta'_t \right) \Sigma_h \right) \geq \mu_1 \left( \frac{1}{n} \sum_i \theta_t \theta'_t \right) \mu_m (\Sigma_h)^2 \). From Assumption 1, the conclusion follows.

### A.4.5 Proof of Lemma 5

We start with the case \( k = 1 \), and then extend the arguments to the case \( k \geq 2 \).

**a)** When \( k = 1 \), let us consider matrix \( \tilde{A} = \frac{1}{nT} \sum_i \theta_t^2 \tilde{H}_i \tilde{H}'_i = (\tilde{a}_{t,s}) \) with elements \( \tilde{a}_{t,s} = \frac{1}{nT} \sum_i I_{i,t} I_{i,s} \theta_t^2 h_t h_s =: a_{t,s} h_t h_s \). Further, define matrices \( A = (a_{t,s}) \) and \( D = \text{diag}(h_t : t = 1, \ldots, T) \). Then \( \tilde{A} = DAD \), and both \( \tilde{A} \) and \( A \) are positive semidefinite matrices. In the first step of the
proof, we show that:
\[ \mu_2(\tilde{A}) \leq M^2 \mu_2(A), \] (26)
where \( M \) is the constant in Assumption A.5 a).

Let \( G \) be a linear subspace of \( \mathbb{R}^T \) and consider the maximization problem \( \max_{x \in G : \|x\| = 1} x' \tilde{A} x = \max_{x \in \mathcal{G} : \|x\| = 1} x' DADx \). For \( x \in G \) such that \( \|x\| = 1 \), define \( y = Dx \). Then, \( y \in D(\mathcal{G}) \) (the image of space \( \mathcal{G} \) under the linear mapping defined by matrix \( D \)) and \( \|y\|^2 \leq \|h\|_{\infty,T}^2 \|x\|^2 = \|h\|_{\infty,T}^2 \leq M^2 \), where \( \|h\|_{\infty,T} = \max_{t=1,...,T} |h_t| \leq M \) under Assumption A.5 a). Then:
\[ \max_{x \in G : \|x\|=1} x' \tilde{A} x \leq \max_{y \in D(\mathcal{G}) : \|y\| \leq M} y' Ay = M^2 \max_{y \in D(\mathcal{G}) : \|y\|=1} y' Ay. \] (27)
Suppose that \( h_t \neq 0 \) for all \( t = 1,...,T \) (an event of probability 1). Then \( D \) corresponds to a one-to-one linear mapping. Let \( \mathcal{F}_1 \) be the eigenspace associated to the largest eigenvalue of matrix \( A \), and define \( \mathcal{G} = D^{-1}(\mathcal{F}_1^+) \), which is a linear subspace of \( \mathbb{R}^T \) with dimension \( T - 1 \). Then, from Inequality (27) we get:
\[ \max_{x \in D^{-1}(\mathcal{F}_1^+) : \|x\|=1} x' \tilde{A} x \leq M^2 \max_{y \in \mathcal{F}_1^+ : \|y\|=1} y' Ay. \] (28)
From the Courant-Fisher min-max theorem (13), we have: \( \mu_2(\tilde{A}) \leq \max_{x \in D^{-1}(\mathcal{F}_1^+) : \|x\|=1} x' \tilde{A} x \), and, from the Courant-Fisher formula (15), we have: \( \mu_2(A) = \max_{y \in \mathcal{F}_1^+ : \|y\|=1} y' Ay \). Then, Inequality (28) implies bound (26).

Finally, let us bound \( \mu_2(A) \). By writing \( A = \frac{1}{nT} (B + C) (B + C)' \), where \( B = (b_{t,i}) \) and \( C = (c_{t,i}) \) are \( T \times n \) matrices with elements \( b_{t,i} = \theta_i \bar{I}_t \) and \( c_{t,i} = \theta_i (I_{i,t} - \bar{I}_t) \), the Weyl inequality (11) implies
\[ \mu_2(A)^{1/2} \leq \mu_2 \left( \frac{1}{nT} BB' \right)^{1/2} + \mu_1 \left( \frac{1}{nT} CC' \right)^{1/2} = \mu_1 \left( \frac{1}{nT} CC' \right)^{1/2}, \] where matrix \( BB' \) has rank 1.

Now \( \frac{1}{nT} CC' = \frac{1}{nT} \tilde{C} \tilde{D} \tilde{C}' \), where the elements of the \( T \times n \) matrix \( \tilde{C} \) are \( \tilde{c}_{t,i} = I_{i,t} - \bar{I}_t \) and \( D \) is a \( n \times n \) diagonal matrix with elements \( \theta^2 \). From Assumption A.5b), we have
\[ \mu_1 \left( \frac{1}{nT} CC' \right) \leq M^2 \mu_1 \left( W \right), \] where the elements of matrix \( W = \frac{1}{nT} \tilde{C} \tilde{D} \tilde{C}' \) are \( w_{t,s} = \frac{1}{nT} \sum_i (I_{i,t} - \bar{I}_t) (I_{i,s} - \bar{I}_s) \). Thus, from Assumption A.11, we get \( \mu_2(A) = O_p(C^{-2}) \). From bound (26), the conclusion follows.

b) Let us now consider the case \( k \geq 1 \). Consider the matrix \( \tilde{A} = \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta'_i \tilde{H}'_i = (\tilde{a}_{t,s}) \) with elements \( \tilde{a}_{t,s} = \frac{1}{nT} \sum_i I_{i,s} I_{i,t} \theta'_i \theta'_i h_{s,t} = \sum_{m,l} \left( \frac{1}{nT} \sum_i I_{i,s} \theta_i \theta_{i,m} \theta_{i,l} \right) h_{t,m} h_{s,l} =: \sum_{m,l} a_{t,s}^{(m,l)} h_{t,m} h_{s,l} \), where
sum\, w.r.t. \, m, \, l \, \text{is from} \, 1 \, \text{to} \, k. \, \text{Then, we have} \, \tilde{A} = \sum_{m,l} D^{(m)} A^{(m,l)} D^{(l)} = D A D', \, \text{where} \, A^{(m,l)} = [a_{t,s}^{(m,l)}], \, D^{(m)} = \text{diag}(h_{t,m} : t = 1, \ldots, T), \, \text{the} \, T \times (T+1) \, \text{matrix} \, D \, \text{is defined by} \, D = [D^{(1)} : \ldots : D^{(k)}] \, \text{and} \, A \, \text{is the} \, (T+1) \times (T+1) \, \text{block matrix with blocks} \, A^{(m,l)}. \\

**Lemma 10** Let \( \begin{pmatrix} A & B \\ B' & D \end{pmatrix} \) be a positive definite (or semi-definite) block matrix. Then, \( \begin{pmatrix} A & B \\ B' & D \end{pmatrix} \leq 2 \begin{pmatrix} A & 0 \\ 0 & D \end{pmatrix} \), where the inequality is w.r.t. the ranking of symmetric matrices.

By repeated application of Lemma 10, we get: \( A \leq 2^{k-1} \begin{pmatrix} A^{(1,1)} & \cdots \\ & \ddots \\ & & A^{(k,k)} \end{pmatrix} \). This implies \( \tilde{A} \leq 2^{k-1} \sum_{m} D^{(m)} A^{(m,m)} D^{(m)}. \) Since two symmetric matrices are ranked if, and only if, their corresponding eigenvalues are ranked, we get:

\[
\mu_{k+1}(\tilde{A}) \leq 2^{k-1} \mu_{k+1} \left( \sum_{m} D^{(m)} A^{(m,m)} D^{(m)} \right).
\]  

(29)

Moreover, we use the next lemma.

**Lemma 11** For \( k \) symmetric matrices \( A_1, A_2, \ldots A_k, \mu_{k+1}(A_1 + \ldots + A_k) \leq \mu_2(A_1) + \ldots + \mu_2(A_k). \)

From Inequality (29) and Lemma 11, we get: \( \mu_{k+1}(\tilde{A}) \leq 2^{k-1} \sum_{m} \mu_2 \left( D^{(m)} A^{(m,m)} D^{(m)} \right) \). By using the arguments deployed for the case \( k = 1 \) in part a), we have \( \mu_2(D^{(m)} A^{(m,m)} D^{(m)}) \leq M^2 \mu_2(A^{(m,m)}). \)

Therefore, we get \( \mu_{k+1}(\tilde{A}) \leq 2^{k-1} M^2 \sum_{m} \mu_2(A^{(m,m)}). \) As in part a), the Weyl inequality and Assumptions A.5b) and A.11 imply \( \mu_2(A^{(m,m)}) \leq M^2 \mu_1(W) = O_p(C_{n,T}^{-2}). \) Thus \( \mu_{k+1}(\tilde{A}) = O_p(C_{n,T}^{-2}). \)

**A.4.6 Proof of Lemma 6**

From the Courant-Fisher max-min Theorem (14), we have:

\[
\mu_{k+1} \left( \frac{1}{nT} \sum_{i} \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right) = \max_{G : \dim(G) = k+1} \min_{x \in G : \|x\| = 1} x' \left( \frac{1}{nT} \sum_{i} \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right) x,
\]

(30)

where the maximization is w.r.t. the linear \((k+1)\)-dimensional subspace \( G \) of \( \mathbb{R}^T \). From Assumption 1 (i), under model \( M_2(k) \) matrix \( H/\sqrt{T} \) has full column-rank equal to \( m \), w.p.a. 1, with \( m \geq k+1 \). Thus, for
any linear subspace $A$ of $\mathbb{R}^m$ with dimension $k + 1$, the set $G_A := \left\{ x \in \mathbb{R}^T : x = \frac{1}{\sqrt{T}} Ha, a \in A \right\}$ is a linear subspace of $\mathbb{R}^T$ of dimension $k + 1$. We deduce from (30):

$$
\mu_{k+1} \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right) \geq \max_{A : \dim(A) = k + 1} \min_{x \in G_A \cap \|x\| = 1} \frac{x' \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right) x}{\min_{a \in A : \|a\| = 1} a' \left( \frac{1}{T} \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' H \right) a}.
$$

By similar arguments as in the proof of Lemma 4, under Assumptions A.8 and A.9, we get the inequality:

$$
\mu_{k+1} \left( \frac{1}{nT} \sum_i \tilde{H}_i \theta_i \theta_i' \tilde{H}_i' \right) \geq C \max_{A : \dim(A) = k + 1} \min_{a \in A : \|a\| = 1} a' \Sigma_h \left( \frac{1}{n} \sum_i \theta_i \theta_i' \right) \Sigma_h a,
$$

w.p.a. 1. By the max-min Theorem, the r.h.s. is such that:

$$
\max_{A : \dim(A) = k + 1} \min_{a \in A : \|a\| = 1} a' \Sigma_h \left( \frac{1}{n} \sum_i \theta_i \theta_i' \right) \Sigma_h a = \mu_{k+1} \left( \Sigma_h \left( \frac{1}{n} \sum_i \theta_i \theta_i' \right) \Sigma_h \right).
$$

Moreover, from inequality (12) for the eigenvalues of product matrices applied twice, we have

$$
\mu_{k+1} \left( \Sigma_h \left( \frac{1}{n} \sum_i \theta_i \theta_i' \right) \Sigma_h \right) \geq \mu_{k+1} \left( \left( \frac{1}{n} \sum_i \theta_i \theta_i' \right) \mu_m (\Sigma_h)^2 \right).
$$

Then, from Assumptions 1 (i) and 4, the conclusion follows.
A.4.7 Proof of Lemma 7

A.4.7.1 Proof of Part (i)

By the serial independence of the error terms, we have:

\[
\frac{1}{n^2T^2} \sum_{i,j} \sum_{t_1,t_2,t_3,t_4} E \left[ u_{i,t_1} u_{i,t_2} u_{j,t_3} u_{j,t_4} \mid x_{i,T}, x_{i,T}, \gamma_i, \gamma_j \right] = \frac{1}{n^2T^2} \sum_{i,j} \sum_{t_1} \sum_{t_2 \neq t_1} E \left[ u_{i,t_1} u_{i,t_1} \mid \gamma_i \right] E \left[ u_{j,t_2} u_{j,t_2} \mid \gamma_j \right] + \frac{1}{n^2T^2} \sum_{i,j} \sum_{t_1 \neq t_2} E \left[ u_{i,t_1} u_{j,t_1} \mid \gamma_i, \gamma_j \right] E \left[ u_{i,t_2} u_{j,t_2} \mid \gamma_i, \gamma_j \right].
\]

The conclusion follows by taking absolute values and expectation, and using the triangular inequality, the Cauchy-Schwarz inequality and Assumption A.2.

A.4.7.2 Proof of Part (ii)

Here, we treat \( \varepsilon_{i,t} \) as a random variable but not through the random draw \( \gamma_i \). This avoids the notational burden coming from conditional expectations. We show directly the inequality

\[
\frac{1}{n^k} \sum_{i_1, \ldots, i_k} \sum_{t_1, \ldots, t_k} |E[e_{i_1,t_1} e_{i_2,t_2} \cdots e_{i_k,t_k}]| \leq M^k,
\]

which implies Assumption A.3. Under Assumption BD.1, there are \( b = b_n \) blocks of approximate size \( d = d_n \), where \( bd = O(n) \).

1) Let \( \omega > 0 \) be such that \( E[\varepsilon_{i,t}^2] \leq \omega^2 \), for all \( i \) and \( t \), and define \( \phi_{i,t} = e_{i,t}/\omega \). The scaled \( \phi_{i,t} \) are such that \( E[\phi_{i,t}] = 0 \), \( E[\phi_{i,t}^2] \leq 1 \), and \( E[|\phi_{i,t}|^r] = O(\delta^{r-2}) \), for all \( r \geq 3 \), uniformly in \( i \) and \( t \). Note that \( \phi_{i,t} \) is a (nonlinear) transformation of \( \varepsilon_{i,t} \). Hence, the variables \( \phi_{i,t} \) have the same block dependence structure.
as the variables $\varepsilon_{i,t}$. Moreover:
\[
\frac{1}{n^k} \sum_{i_1, \ldots, i_k} \sum_{t_1, \ldots, t_k} |E[\varepsilon_{i_1,t_k} \varepsilon_{i_1,t_1} \varepsilon_{i_2,t_1} \cdots] | \\
\leq \omega^k \frac{1}{n^k} \sum_{i_1, \ldots, i_k} \sum_{t_1, \ldots, t_k} |E[\phi_{i_1,t_k} \phi_{i_1,t_1} \phi_{i_2,t_1} \phi_{i_3,t_2} \cdots] | \\
=: \omega^k I_k. \tag{31}
\]

Let us now bound $I_k$.

2) For $m = 1, \ldots, k$, let $C_m$ denote the set of $k$-tuples $(i_1, \ldots, i_k)$ such that indices $i_1, \ldots, i_k$ belong to $m$ different blocks. Let $N_m$ denote the number of different 2$k$-tuples $(i_1, \ldots, i_k)$, $(t_1, \ldots, t_k)$ such that $(i_1, \ldots, i_k) \in C_m$ and the expectation $E[\phi_{i_1,t_k} \phi_{i_1,t_1} \phi_{i_2,t_1} \phi_{i_3,t_2} \cdots] \phi_{i_{k-1},t_{k-1}} \phi_{i_k,t_k} \phi_{i_k,t_k} \phi_{i_k,t_k}$ does not vanish. Moreover, let $Q_m$ be an upper bound for such a non-vanishing expectation. Then:
\[
I_k \leq \frac{1}{n^k} \sum_{m=1}^k N_m Q_m. \tag{32}
\]

3) We need upper bounds for $N_m$ and $Q_m$, for $m = 1, 2, \ldots, k$, and any integer $k$.

- $m = 1$: The number of $k$-tuples $(i_1, \ldots, i_k)$ with all indices in the same block is $O(bd^k)$. Indeed, we can select the block among $b$ alternatives, and we have $O(d^k)$ possibilities to select the indices within the block. Then, $N_1 = O(bd^k T_k)$. Moreover, by the Cauchy-Schwarz inequality,
\[
E[\phi_{i_1,t_k} \phi_{i_1,t_1} \phi_{i_2,t_1} \phi_{i_3,t_2} \cdots] \phi_{i_{k-1},t_{k-1}} \phi_{i_k,t_k} \phi_{i_k,t_k} \phi_{i_k,t_k} \leq \sup_{i,t} E[|\phi_{i,t}|^{2k}] = O(\delta^{2k-2}).
\]
Thus, $Q_1 = O(\delta^{2(k-1)})$.

- $m = k$: The number of $k$-tuples $(i_1, \ldots, i_k)$ with indices in $k$ different blocks is $O(b^k d^k)$. For such a $k$-tuple:
\[
E[\phi_{i_1,t_k} \phi_{i_1,t_1} \phi_{i_2,t_1} \phi_{i_3,t_2} \cdots] \phi_{i_{k-1},t_{k-1}} \phi_{i_k,t_k} \phi_{i_k,t_k} = E[\phi_{i_1,t_k} \phi_{i_1,t_1}] E[\phi_{i_2,t_1} \phi_{i_2,t_2}] \cdots E[\phi_{i_k,t_{k-1}} \phi_{i_k,t_k}].
\]
Hence, the indices $t_1, \ldots, t_k$ must be all equal for this expectation not to vanish. Then, $N_k = O(b^k d^k T_k)$ and $Q_k \leq 1$.

\footnote{For $k > b$, there are no $k$-tuples $(i_1, \ldots, i_k)$ with indices in $k$ different blocks, and $N_k = 0$. The upper bound $N_k = O(b^k d^k T_k)$ trivially holds also in this case. However, this case will not occur with our choice of sequence $k$, since (37) implies $k = o(b)$, see below.}
• \( m = 2 \): The number \( N_2 \) is \( O(b^2) \times \binom{k}{2} \times O(d^k) \times O(T^{k-1}) \), where \( \binom{k}{2} = 2^{k-1} - 1 \) is the number of different ways in which we can divide \( k \) objects into two (non-empty) groups (a Stirling number of the second kind). Indeed, \( O(b^2) \) is a bound for the number of different ways to select the two distinct blocks. Then, for each \( j = 1, \ldots, k \) we select whether index \( i_j \) is in the first or the second block; we have \( \binom{k}{2} \) different possibilities. Once we have fixed the blocks, we have \( O(d^k) \) alternatives to select the indices. By block dependence, the expectation \( E[\phi_{i_1, t_k} \phi_{i_1, t_1} \phi_{i_2, t_2} \cdots \phi_{i_k, t_{k-1}} \phi_{i_k, t_k}] \) can be splitted into two expectations, and at least a pair of indices in the \( k \)-tuple \((t_1, \ldots, t_k)\) must be equal for the expectation not to vanish. Hence the term \( O(T^{k-1}) \).

Suppose the expectation \( E[\phi_{i_1, t_k} \phi_{i_1, t_1} \phi_{i_2, t_2} \cdots \phi_{i_k, t_{k-1}} \phi_{i_k, t_k}] \) is splitted into two expectations, with \( r_1 \) indices \( i_j \) in the first block, and \( r_2 \) indices in the second block, \( r_1 + r_2 = k \). Then, \( E[\phi_{i_1, t_k} \phi_{i_1, t_1} \phi_{i_2, t_2} \cdots \phi_{i_k, t_{k-1}} \phi_{i_k, t_k}] = O(\delta^2(r_1-1)) \times O(\delta^2(r_2-1)) = O(\delta^2(k-2)) \). Hence, \( Q_2 = O(\delta^2(k-2)) \).

• Generic \( m \): We have

\[
N_m = O(b^m) \times \binom{k}{m} \times O(d^k) \times O(T^{k-m+1}),
\]
\[
Q_m = O(\delta^2(k-m)),
\]

where the Stirling number of the second kind \( \binom{k}{m} = \frac{1}{m!} \sum_{j=0}^{m} (-1)^{m-j} \binom{m}{j} j^k \) gives the number of different ways in which we can divide \( k \) objects into \( m \) (non-empty) groups (see e.g. Rennie and Dobson (1969)) and \( \binom{k}{m} \) is a binomial coefficient.

From bounds (32), (33) and (34), and using \( d = O(n/b) \), we get:

\[
I_k \leq \frac{\text{const}}{n^k} \sum_{m=1}^{k} b^m d^k \binom{k}{m} T^{k-m+1} \delta^2(k-m)
= \text{const} \times T \sum_{m=1}^{k} \binom{k}{m} (\delta^2T/b)^{k-m}.
\]

4) We exploit the following upper bound for the Stirling numbers of the second kind (see Rennie and Dobson (1969), Theorem 3)

\[
\binom{k}{m} \leq \frac{1}{2} \binom{k}{m} m^{k-m}.
\]

Then, we get:

\[
\sum_{m=1}^{k} \binom{k}{m} (\delta^2T/b)^{k-m} \leq
\]

Electronic copy available at: https://ssrn.com/abstract=2817458
\[ \frac{1}{2} \sum_{m=1}^{k} m^{k-m} \binom{k}{m} (\delta^2 T/b)^{k-m} \leq \frac{1}{2} \sum_{m=0}^{k} \binom{k}{m} (k\delta^2 T/b)^{k-m} = \frac{1}{2} (1 + k\delta^2 T/b)^k, \] from the binomial theorem. Thus, from (35), we get:

\[ I_k \leq \text{const} T (1 + k\delta^2 T/b)^k. \] (36)

5) Assume that the sequence \( k = k_n \uparrow \infty \) is such that:

\[ k\delta^2 T/b = o(1), \quad T = O(e^k). \] (37)

From (36) and (37), we get \( I_k \leq (2e)^k \). Then, from (31):

\[ \frac{1}{n^k} \sum_{i_1, \ldots, i_k, t_1, \ldots, t_k} |E[e_{i_1, t_1} e_{i_1, t_1} e_{i_2, t_2} e_{i_2, t_2} \cdots e_{i_k, t_k} e_{i_k, t_k}]| \leq (2e\omega)^k, \]

i.e., the bound in Assumption A.3 holds with \( C = 2e\omega \).

6) Let us now verify the compatibility of the different rates, i.e., that we can choose sequences \( \delta = n^\beta \) and \( k = c \log(n) \), \( \beta, c > 0 \), such that \( \sqrt{T}/\delta^{q-1} = o(1) \), \( \beta > 2/q \), and they match conditions (37). Let \( n \geq T^{1/\gamma} \) and \( b \geq n^\alpha \), with \( \gamma < 1 \) and \( \alpha \in (0, 1] \). Condition \( T = O(e^k) \) is satisfied if \( c \geq \gamma \). Condition \( k\delta^2 T/b = o(1) \) implies:

\[ \beta < \frac{1}{2} (\alpha - \gamma). \] (38)

Condition \( \sqrt{T}/\delta^{q-1} = o(1) \) implies \( \beta > \frac{\gamma}{2(q-1)} \). The latter inequality is implied by

\[ \beta > \frac{2}{q}, \] (39)

since \( \gamma < 1 \) and \( q \geq 8 \) in Assumption A.2. Then, there exists a power \( \beta > 0 \) satisfying conditions (38) and (39) if, and only if, \( \frac{1}{2} (\alpha - \gamma) > \frac{2}{q} \), which corresponds to Condition (22). This condition clarifies the link between the behaviour of expectations of products of error terms and the assumption of a bounded largest eigenvalue used for example in Chamberlain and Rothschild (1983) p. 1294 for arbitrage pricing theory.
A.4.8 Proof of Lemma 8

We follow the arguments in the proof of Lemma 2.2 in Yin et al. (1988). From the conditions \( \delta \geq n^\beta \) and \( T \leq C_2 n \), we have:

\[
P(\mathcal{E} \neq \Xi \text{ i.o.}) \leq \lim_{k \to \infty} \sum_{m=k}^{\infty} P \left( \bigcup_{2^{m-1} \leq n < 2^m} \bigcup_{i=1}^{n} \bigcup_{t=1}^{T} \{|\varepsilon_{i,t}| > \delta\} \right)
\]

\[
\leq \lim_{k \to \infty} \sum_{m=k}^{\infty} P \left( \bigcup_{i=1}^{n} \bigcup_{t=1}^{T} \{|\varepsilon_{i,t}| > 2^{(m-1)\beta}\} \right)
\]

\[
\leq \lim_{k \to \infty} \sum_{m=k}^{\infty} C_2 2^{2m} P \left(|\varepsilon_{i,t}| > 2^{(m-1)\beta}\right).
\]

Thus, part (i) follows from the summability condition:

\[
\sum_{m=1}^{\infty} 2^{2m} P \left(|\varepsilon_{i,t}| > 2^{(m-1)\beta}\right) < \infty.
\] (40)

To prove the summability condition (40), we use the Chebyshev inequality and Assumption A.2. We have

\[
P \left(|\varepsilon_{i,t}| > 2^{(m-1)\beta}\right) \leq \frac{E[|\varepsilon_{i,t}|^{q}]/2^{(m-1)\beta q}}{2^{(m-1)\beta q}} \leq \frac{M/2^{(m-1)\beta q}}{2^{(m-1)\beta q}}.
\]

Therefore, we get:

\[
\sum_{m=1}^{\infty} 2^{2m} P \left(|\varepsilon_{i,t}| > 2^{(m-1)\beta}\right) \leq M \sum_{m=1}^{\infty} \frac{2^{2m}}{2^{(m-1)\beta q}} = M2^{\beta q} \sum_{m=1}^{\infty} 2^{(\beta q-2)m} < \infty,
\]

since \( q\beta > 2 \).

Part (ii) is a straightforward consequence of part (i), since \( P(\tilde{\mathcal{E}} \neq \tilde{\Xi} \text{ i.o.}) \leq P(\mathcal{E} \neq \Xi \text{ i.o.}) \).

A.4.9 Proof of Lemma 9

We follow the arguments in Bai and Yin (1993), p. 1278. We use the von Neumann inequality (von Neumann (1937)): for any \( n \times T \) matrices \( A \) and \( B \),

\[
tr(A'B) \leq \sum_{k=1}^{T} \mu_k(A'A)^{1/2} \mu_k(B'B)^{1/2}.
\] (41)

We have:

\[
\left[ \mu_1^{1/2} \left( \frac{1}{n} \tilde{\Xi} \tilde{\Xi}' \right) - \mu_1^{1/2} \left( \frac{1}{n} \tilde{E} \tilde{E}' \right) \right]^2 \leq \sum_{k=1}^{T} \left[ \mu_k^{1/2} \left( \frac{1}{n} \tilde{\Xi} \tilde{\Xi}' \right) - \mu_k^{1/2} \left( \frac{1}{n} \tilde{E} \tilde{E}' \right) \right]^2
\]

\[
= tr \left( \frac{1}{n} \tilde{\Xi} \tilde{\Xi}' \right) + tr \left( \frac{1}{n} \tilde{E} \tilde{E}' \right) - 2 \sum_{k=1}^{T} \mu_k^{1/2} \left( \frac{1}{n} \tilde{\Xi} \tilde{\Xi}' \right) \mu_k^{1/2} \left( \frac{1}{n} \tilde{E} \tilde{E}' \right).
\]
The last term in the r.h.s. is bounded by the von Neumann inequality (41):

$$
\left[ \mu_1^{1/2} \left( \frac{1}{n} \tilde{\Xi} \tilde{\Xi}' \right) - \mu_1^{1/2} \left( \frac{1}{n} \tilde{E} \tilde{E}' \right) \right]^2 \leq \text{tr} \left( \frac{1}{n} \tilde{\Xi} \tilde{\Xi}' \right) + \text{tr} \left( \frac{1}{n} \tilde{E} \tilde{E}' \right) - 2 \frac{1}{n} \text{tr} \left( \tilde{\Xi} \tilde{E}' \right)
= \frac{1}{n} \text{tr} \left[ (\tilde{\Xi} - \tilde{E})(\tilde{\Xi} - \tilde{E})' \right]. \tag{42}
$$

The elements of matrix \( \tilde{\Xi} - \tilde{E} \) are \( I_{i,t}E[\varepsilon_{i,t}1\{\varepsilon_{i,t} \leq \delta\} \gamma_i] \). By the zero-mean property of the errors \( \varepsilon_{i,t} \), the Minkowski inequality and Assumption A.2, we have:

$$
|E[\varepsilon_{i,t}1\{\varepsilon_{i,t} \leq \delta\}]| = |E[\varepsilon_{i,t}1\{\varepsilon_{i,t} > \delta\}]| \leq E[|\varepsilon_{i,t}|^q]^{1/q}P[|\varepsilon_{i,t}| > \delta]^{1/q},
$$

where \( 1/q + 1/\bar{q} = 1 \), with \( q \) defined in Assumption A.2. By the Chebyshev inequality and Assumption A.2, we get:

$$
E[|\varepsilon_{i,t}|^q]^{1/q}P[|\varepsilon_{i,t}| > \delta]^{1/q} \leq E[|\varepsilon_{i,t}|^q]^{1/q} \left( \frac{E[|\varepsilon_{i,t}|^q]}{\delta^q} \right)^{1/q} \leq \frac{M}{\delta^{q-1}}.
$$

Thus, we get:

$$
\frac{1}{n} \text{tr} \left[ (\tilde{\Xi} - \tilde{E})(\tilde{\Xi} - \tilde{E})' \right] = \frac{1}{n} \sum_i \sum_t I_{i,t}E[\varepsilon_{i,t}1\{\varepsilon_{i,t} \leq \delta\}]^2 \leq \frac{T M^2}{\delta^{2(q-1)}}. \tag{43}
$$

From inequalities (42) and (43), we get \( |\mu_1^{1/2} \left( \frac{1}{n} \tilde{\Xi} \tilde{\Xi}' \right) - \mu_1^{1/2} \left( \frac{1}{n} \tilde{E} \tilde{E}' \right) | \leq \sqrt{T} \frac{M}{\delta^{q-1}}. \) Since the sequence \( \delta = \delta_n \) is such that \( \sqrt{T}/\delta^{q-1} = o(1) \), the conclusion follows.

### A.4.10 Proof of Lemma 10

We have:

$$
2 \begin{pmatrix} A & 0 \\ 0 & D \end{pmatrix} - \begin{pmatrix} A & B \\ B' & D \end{pmatrix} = \begin{pmatrix} A & -B \\ -B' & D \end{pmatrix},
$$

and:

$$
\begin{pmatrix} x_1' & x_2' \\ x_1 & x_2 \end{pmatrix} \begin{pmatrix} A & -B \\ -B' & D \end{pmatrix} \begin{pmatrix} x_1' \\ x_2 \end{pmatrix} = \begin{pmatrix} x_1' & -x_2' \\ x_1 & -x_2 \end{pmatrix} \begin{pmatrix} A & B \\ B' & D \end{pmatrix} \begin{pmatrix} x_1 \\ -x_2 \end{pmatrix} \geq 0,
$$

for all \( x = (x_1', x_2'). \)
A.4.11 Proof of Lemma 11

By repeated application of the Weyl inequality for eigenvalues (see Appendix 2 (i)) we have:

\[ \mu_{k+1}(A_1 + \ldots + A_k) \leq \mu_k(A_1 + \ldots + A_{k-1}) + \mu_2(A_k) \]
\[ \leq \mu_{k-1}(A_1 + \ldots + A_{k-2}) + \mu_2(A_{k-1}) + \mu_2(A_k) \]
\[ \ldots \]
\[ \leq \mu_2(A_1) + \ldots + \mu_2(A_k). \]

Appendix 5 Verification that conditional independence implies Assumption 2

Let us verify that Assumption 2 is true if the latent factors are independent of the lagged stock-specific instruments, conditional on the observable factors and the lagged common instruments.

We have:

\[ h_t \perp \{Z_{i,t-1}, i = 1, \ldots\} \mid f_t, Z_{t-1} \Rightarrow h_t \perp \{\tilde{x}_{i,t}, i = 1, \ldots\} \mid f_t, Z_{t-1} \]
\[ \Rightarrow h_t \perp \{\tilde{x}_{i,t}, i = 1, \ldots\} \mid x_t \]
\[ \Rightarrow EL[h_t|x_{i,t}, i = 1, \ldots] = EL[h_t|x_t], \]

where \( A \perp B|C \) denotes independence of \( A \) and \( B \) conditional on \( C \).
SUPPLEMENTARY MATERIALS

A diagnostic criterion for approximate factor structure

Patrick Gagliardini, Elisa Ossola and Olivier Scaillet

These supplementary materials provide the link with Stock and Watson (2002) (Appendix 6), and the results of Monte-Carlo experiments (Appendix 7).

Appendix 6  Link with Stock and Watson (2002)

We consider the EM algorithm proposed by Stock and Watson (2002) applied to residuals \( \hat{\varepsilon}_{i,t} \):

\[
\tilde{\varepsilon}_{i,t} = \begin{cases} 
\hat{\varepsilon}_{i,t}, & \text{if } I_{i,t} = 1, \\
\hat{\theta}_t \hat{h}_t, & \text{if } I_{i,t} = 0.
\end{cases}
\]

Let us define the criterion \( \xi_{SW} = \mu_1 \left( \frac{\| \tilde{\varepsilon} \|}{nT} \right) - \frac{1}{nT} \sum_i \sum_t (1 - I_{i,t}) (\hat{\theta}_t \hat{h}_t)^2 - g(n, T) \). Below we show that \( \xi_{SW} \) is the penalized difference of the EM criteria under the two rival models. Comparing the criteria \( \xi \) and \( \xi_{SW} \) gives the following link:

\[
\frac{1}{nT} \sum_i \sum_t (1 - I_{i,t}) (\hat{\theta}_t \hat{h}_t)^2 = \frac{1}{nT} \| \tilde{\varepsilon} - \hat{\varepsilon} \|^2.
\]

To study the EM algorithm, we work as if the true error terms \( \varepsilon_{i,t} \) are observed when \( I_{i,t} = 1 \). This error is replaced by the residual \( \hat{\varepsilon}_{i,t} \). We consider the \( j \)th iteration of the algorithm. Let \( \hat{\zeta} = (\hat{\Theta}, \hat{H}) \) denotes the estimates of \( \Theta \) and \( H \) obtained from the \( (j - 1) \)th iteration, and let \( Q \left( \zeta, \hat{\zeta} \right) = E_{\hat{\zeta}} \left[ L(\zeta) | \varepsilon \right] \), where \( L(\zeta) = \frac{1}{nT} \sum_i \sum_t (\varepsilon_{i,t}^* - \theta_i h_t)^2 \), and \( E_{\hat{\zeta}}[\cdot | \varepsilon] \) denotes conditional expectation given the panel of observations under parameter \( \hat{\zeta} \). We study \( Q \left( \zeta, \hat{\zeta} \right) \) under the two models. Under both \( \mathcal{M}_1 \) and \( \mathcal{M}_2 \), we consider a pseudo model for the innovations such that \( u_{i,t} \sim \text{i.i.d.} \left( 0, \sigma_{i,t}^2 \right) \).

- Under \( \mathcal{M}_1 \): we get

\[
Q_0 \left( \zeta, \hat{\zeta} \right) = E \left[ \frac{1}{nT} \sum_i \sum_t (\varepsilon_{i,t}^*)^2 | \varepsilon \right] = \frac{1}{nT} \sum_i \sum_t E \left[ (\varepsilon_{i,t}^*)^2 | \varepsilon \right].
\]
We have

\[ E \left[ \varepsilon_{i,t}^* | \varepsilon \right] = \begin{cases} \varepsilon_{i,t}, & \text{if } I_{i,t} = 1, \\ 0, & \text{if } I_{i,t} = 0, \end{cases} \quad \text{and } V \left[ \varepsilon_{i,t}^* | \varepsilon \right] = \begin{cases} \varepsilon_{i,t}, & \text{if } I_{i,t} = 1, \\ 0, & \text{if } I_{i,t} = 0. \end{cases} \]

and \( E \left[ (\varepsilon_{i,t}^*)^2 | \varepsilon \right] = I_{i,t} \varepsilon_{i,t}^2 + (1 - I_{i,t}) \sigma_{i,t}^2 \). Thus,

\[ Q_0 = Q_0 (\zeta, \tilde{\zeta}) = \frac{1}{nT} \sum_i \sum_t I_{i,t} \varepsilon_{i,t}^2 + \frac{1}{nT} \sum_i \sum_t (1 - I_{i,t}) \sigma_{i,t}^2. \]

- Under \( M_2 \): we get

\[ Q_1 (\zeta, \tilde{\zeta}) = E_{\tilde{\zeta}} \left[ \frac{1}{nT} \sum_i \sum_t (\varepsilon_{i,t}^* - \theta_{i,t} h_t)^2 | \varepsilon \right] = \frac{1}{nT} \sum_i \sum_t E_{\tilde{\zeta}} \left[ (\varepsilon_{i,t}^* - \theta_{i,t} h_t)^2 \right] = \frac{1}{nT} \sum_i \sum_t V_{\tilde{\zeta}} \left[ \varepsilon_{i,t}^* | \varepsilon \right] + \frac{1}{nT} \sum_i \sum_t \left( E_{\tilde{\zeta}} \left[ \varepsilon_{i,t}^* | \varepsilon \right] - \theta_{i,t} h_t \right)^2. \]

We have

\[ \tilde{\varepsilon}_{i,t} := E_{\tilde{\zeta}} \left[ \varepsilon_{i,t}^* | \varepsilon \right] = \begin{cases} \varepsilon_{i,t}, & \text{if } I_{i,t} = 1, \\ \hat{\theta}_t h_t, & \text{if } I_{i,t} = 0, \end{cases} \quad \text{and } V \left[ \varepsilon_{i,t}^* | \varepsilon \right] = \begin{cases} \varepsilon_{i,t}, & \text{if } I_{i,t} = 1, \\ 0, & \text{if } I_{i,t} = 0. \end{cases} \]

Thus, \( Q_1 (\zeta, \tilde{\zeta}) = \frac{1}{nT} \sum_i \sum_t (\tilde{\varepsilon}_{i,t} - \theta_{i,t} h_t)^2 + \frac{1}{nT} \sum_i \sum_t (1 - I_{i,t}) \sigma_{i,t}^2 \), and the values of \( \zeta \) that minimize \( Q_1 (\zeta, \tilde{\zeta}) \) can be calculated by \( \min \zeta \frac{1}{nT} \sum_i \sum_t (\tilde{\varepsilon}_{i,t} - \theta_{i,t} h_t)^2 \). This minimization problem reduces to the usual PCA on data \( \tilde{\varepsilon} \):\( \min \zeta \frac{1}{nT} \sum_i \sum_t (\tilde{\varepsilon}_{i,t} - \theta_{i,t} h_t)^2 = \frac{1}{nT} \sum_i \sum_t \tilde{\varepsilon}_{i,t}^2 - \mu_1 \left( \frac{\tilde{\varepsilon}_{i,t}^2}{nT} \right). \)

Therefore, at convergence with \( \tilde{\zeta} = \zeta \), we have

\[ Q_1 (\tilde{\zeta}, \tilde{\zeta}) = \frac{1}{nT} \sum_i \sum_t \tilde{\varepsilon}_{i,t}^2 - \mu_1 \left( \frac{\tilde{\varepsilon}_{i,t}^2}{nT} \right) + \frac{1}{nT} \sum_i \sum_t (1 - I_{i,t}) \sigma_{i,t}^2 \]

\[ = \frac{1}{nT} \sum_i \sum_t I_{i,t} \tilde{\varepsilon}_{i,t}^2 + \frac{1}{nT} \sum_i \sum_t (1 - I_{i,t}) \left( \hat{\theta}_t h_t \right)^2 - \mu_1 \left( \frac{\tilde{\varepsilon}_{i,t}^2}{nT} \right) + \frac{1}{nT} \sum_i \sum_t (1 - I_{i,t}) \sigma_{i,t}^2. \]
Finally, the difference of the two EM criteria is

\[ Q_0 - Q_1 \left( \hat{\zeta}, \hat{\xi} \right) = \mu_1 \left( \frac{\hat{\xi} \hat{\xi}'}{nT} \right) - \frac{1}{nT} \sum_i \sum_t (1 - I_{i,t}) \left( \hat{\theta}_i \hat{h}_t \right)^2, \]

which gives the criterion \( \xi^{SW} \) after penalization.

**Appendix 7 Monte-Carlo experiments**

From the core text, we know that our selection procedure is equivalent to the penalized least-squares strategy of Bai and Ng (2002) applied on residuals when we use the same penalty term. The first part of our Monte-Carlo experiments in Section A.7.1 aims to show, as expected, that the penalisation introduced in Section 5 delivers a performance similar to the one observed in the literature with other penalisations in the presence of latent factors only. Indeed, we also consider the alternative methods to select the number of factors proposed in Bai and Ng (2002), Onatski (2010), and Ahn and Horenstein (2013). We investigate settings with \( n \) and \( T \) of comparable sizes as well as \( n \) much larger than \( T \), as covered by our theory, starting with balanced panels. Then we investigate how our selection procedure and the other selection criteria perform with unbalanced panels. The main result is that the performance is similar when the operative sizes of an unbalanced panel, i.e., the cross-sectional dimension \( n^X \) and the average \( \bar{T}_i \) of the time-series dimensions \( T_i, \ i = 1, \ldots, n^X \), obtained after trimming, are close to the sizes \( n \) and \( T \) of a balanced panel. Moreover, we show that the several criteria considered work equally well and we cannot find a clear superiority of one over the other.

The second part of our Monte-Carlo experiments in Section A.7.2 aims to extend the performance study to settings where we face observable factors, and apply the selection procedures to residuals. We show that the performances are close to the ones obtained without observable factors.

**A.7.1 Simulations with \( r \) latent factors**

In this section, we perform simulation exercises in the presence of \( r \) latent factors only. We consider both balanced and unbalanced panels in the study of the properties of our diagnostic criterion. In the balanced case, we consider the simulation design in Ahn and Horenstein (2013). We generate \( S = 1,000 \) datasets of
dimension $n \times T$ so that, at each simulation $s = 1, ..., S$,

$$R^s_{i,t} = \sum_{j=1}^{r} b^s_{i,j} f^s_{j,t} + \varepsilon^s_{i,t}, \text{ with } \varepsilon^s_{i,t} = \sqrt{\frac{1 - \rho^2}{1 + 2J\beta^2}} e^s_{i,t}, \text{ for } i = 1, ..., n, \text{ and } t = 1, ..., T, \quad (44)$$

where $e^s_{i,t} = \rho e^s_{i,t-1} + v^s_{i,t} + \sum_{h=\max(i-J,1)}^{i-1} \beta v^s_{h,t} + \sum_{h=i+1}^{\min(i+J,n)} \beta v^s_{h,t}$, and the error term $v^s_{i,t}$, the factor loading $b^s_{i,j}$, and the factor $f^s_{j,t}$ are drawn from standardized normal distributions. Bai and Ng (2002) and Onatski (2010) use a similar data generating process (DGP) in their simulation exercises. The DGP in Equation (44) depends on three parameters: (i) $\rho$ measures the magnitude of the time-series correlation in the idiosyncratic errors $e^s_{i,t}$, (ii) $\beta$ measures the magnitude of the cross-sectional correlation between the errors $e^s_{i,t}$, (iii) $J$ defines the number of units $i$ that are cross-correlated. At each simulation, we compute on the standardized $R^s_{i,t}$ our diagnostic criterion $\xi(k)$. We also maximize (i) the edge distribution (ED) estimator introduced by Onatski (2010), (ii) the eigenvalue ratio (ER) and the growth ratio (GR) estimators described in Ahn and Horenstein (2013), (iii) the criteria $PC_l$, $IC_l$, $AIC_l$ and $BIC_l$, with $l = 1, 2, 3$ proposed by Bai and Ng (2002). We fix the maximum possible number of factors ($k_{max}$) equal to eight as in Ahn and Horenstein (2013). The simulation settings and results provided in Ahn and Horenstein (2013) consider only balanced panels with $n$ and $T$ comparable. Our setting extends their results also to panels characterized by a large cross-sectional dimension. The trimming levels do not affect the number of assets $n$ in the simulations since the panel is balanced and $T$ is sufficiently large. In order to understand how the criteria work in practice, we consider several covariance structures, i.e., several combinations of parameters ($\rho$, $\beta$, $J$), and several combinations of the cross-sectional dimension $n$ and the time-series dimension $T$.

Table 6 reports the selection probability of the correct model estimated from the simulated datasets when $r = 0$, i.e., $Pr(\xi < 0|\mathcal{M}_1)$. The selection probabilities are close to 100% for most combinations of the cross-sectional sample size $n$ and the time-series dimension $T$. Table 6, Panels A-D, compares the selection probabilities when the magnitude of the time-series correlation changes in the error structure. Table 6, Panels E-G contains the results when the magnitude of the cross-sectional correlation increases through the parameters $\beta$ and $J$. The increase of the correlation in the cross-section affects the selection probabilities when the ratio $T/n$ is too far from zero. In Panels F and G, the selection probability falls to zero when $n$ is much smaller than $T$. In Panel G, we can explain $Pr(\xi < 0|\mathcal{M}_1) = 85.30\%$, when $n = T = 150$.
by the cross-sectional correlation being confused with a common latent factor when \( n \) is too small. The magnitude of the cross-sectional correlation in the errors has a larger effect on the selection probabilities than the presence of the time-series correlation in the errors. Indeed, we always select correctly the model in Panels B-D. Table 6 also reports the \( x\% \) of the replications that result in overestimation w.r.t. the \( y\% \) of the replications that result in underestimation of the number of factors for \( r = 3 \). The criterion \( \xi (k) \) introduced in Equation (8) estimates the correct number of unobservable factors for any combinations of \( n \) and \( T \) in the different designs for the error structure. The penalty function is based on a Gaussian reference model, namely \( g(n, T) = c \left( \frac{\sqrt{n} + \sqrt{T}}{nT} \right)^2 \ln \left( \frac{nT}{\left( \sqrt{n} + \sqrt{T} \right)^2} \right) \), where \( c \) is a data-driven constant. The constant is selected as in Alessi et al. (2010) (see also Hallin and Liška (2007) in the general dynamic factor model). The procedure for selecting the constant \( c \) relies on the behavior of the variance of the selected number of factors \( \hat{k}_j (c) \) computed across cross-sectional subsamples \( j = 1, \ldots, 33 \) of increasing size \( (n_j, T) \), for a whole interval for values of the constant \( c \). If the panel is balanced, we choose the smallest value of \( c \) in the second stability interval of the variance (i.e., the second interval of values \( c \) for which the variance of \( \hat{k}_j (c) \) is insensitive to \( c \) as advocated by Alessi et al. (2010)).

The criterion \( \xi (k) \) thus compares well with the other selection methods proposed by the literature. In particular, Table 7 shows that the criterion \( \xi (k) \) performs equally well as the maximization criteria proposed by Bai and Ng (2002), Ahn and Horenstein (2013), and Onatski (2010) when \( r = 3 \) and the error terms \( e_{s,t} \) are either i.i.d. or correlated. The criterion \( \xi (k) \) performs equally well as the criteria \( ED, ER \) and \( GR \) when the error terms are serially and cross-sectionally correlated.

For unbalanced panels, we explore the properties of the diagnostic criterion using a simulation design that mimics the empirical features of our data. We simulate a matrix of observability indicators \( I_s \in \mathbb{R}^{n \times T} \) as follows. We fix an integer \( \min (T_i) \leq T \). For each \( i \), we draw \( T_i \) from a uniform distribution on an interval of integers between \( \min (T_i) \) and \( T \). The \( T_i \) ones for asset \( i \) (\( I_{i,t}^s = 1 \)) are set for consecutive dates starting from a random date \( t_{0,i} \). The draws across individuals \( i \) are independent. We generate \( R_{i,t}^s \) in Equation (44) if \( I_{i,t}^s = 1 \), for \( i = 1, \ldots, n \), and \( t = 1, \ldots, T \). In this framework, the trimming approach is not needed. We keep the cross-sectional dimensions equal to \( n = 150, 500, 1500, 3000, 6000 \). In Table 8, we report the mean of the averages \( \bar{T}_i \) of the time-series sizes \( T_i \), \( i = 1, \ldots, n \), across simulations, as
well as the min and the max of the $T_i$. The choice of the min ($T_i$) in the simulation approach defines the amount of missing values in the simulated sample. Since the effective time-series sizes are smaller than $T$, we need to compensate for this in the penalty function of the diagnostic criterion. Otherwise, we have a tendency to underpenalize and to diagnose a too large number of omitted factors. Thus, we select a constant $c$ larger than the constant selected for balanced panels, namely, we choose the smallest value of $c$ of the third (instead of the second) stability interval of the variance of the selected number of factors. Tables 9-14 report the results for several levels of min ($T_i$). In general, the unbalanced property of the dataset does not seem to deteriorate the selection probabilities of the correct model when $r = 0$ or $r = 3$. We observe a deterioration of the probability of the diagnostic criterion $\xi (k)$ when the time-series size is too short w.r.t. the cross-sectional dimension and the amount of missing values is high (see Panel D in Table 9). Finally, due the unbalanced property, we observe that the selection criteria by Onatski (2010) and Bai and Ng (2002) tend to overestimate the number of factors.

A.7.2 Simulations with one observable factor and $r$ latent factors

In this section, we gauge the impact of estimation error coming from using residuals instead of the true errors in the diagnostic criterion and in the other criteria introduced previously. We repeat the experiments described in the previous section, but with one observable factor and $r$ latent factors in the DGP, so that, at each simulation $s = 1, ..., S$,

$$R_{i,t}^s = B_i F_t + \sum_{j=1}^r b_{i,j}^s f_{j,t}^s + \varepsilon_{i,t}^s,$$

with $\varepsilon_{i,t}^s = \sqrt{\frac{1 - \rho^2}{1 + 2 J \beta^2}} \varepsilon_{i,t}^{s, t}$, for $i = 1, ..., n$, and $t = 1, ..., T$, (45)

where $B_i$ is the factor loading of the single observable factor $F_t$, both initially drawn from standardized normal distributions. At each simulation, we estimate a one-factor model on $R_{i,t}^s$, and we compute the diagnostic criterion on the standardized residuals, when $r = 0$ and $r = 3$. In Tables 15 and 16, we get the results for the balanced case. The performances of the criterion $\xi (k)$ and the other criteria are similar to what we get in Tables 6 and 7. Thus, the presence of observable factors does not corrode the performance of the criteria considered. We conclude similarly for the unbalanced case through comparing the simulation results reported in Tables 17-22 with the ones of Tables 9-14. We only observe a moderate tendency of the criterion $\xi (k)$ to underestimate the number of latent factors when $n$ is too small.
The table contains the probabilities of correct model selection estimated from the simulated balanced dataset when \( r = 0 \) (first row in each panel). For \( r = 3 \), the table reports the percentages \( x\%/y\% \) of the replications that result in overestimation / underestimation of the number of factors (second row in each panel). The \((100 - x - y)\%\) of the replications is the probability of correct estimation of the number of unobservable factors. The simulations are based on the DGP in Equation (44). Panels A-L contain the results assuming different combinations of parameters \( \rho, \beta \) and \( J \).

The table contains the probabilities of correct model selection estimated from the simulated balanced dataset when \( r = 0 \) (first row in each panel). For \( r = 3 \), the table reports the percentages \( x\%/y\% \) of the replications that result in overestimation / underestimation of the number of factors (second row of each panel). The \( (100 - x - y)\% \) of the replications is the probability of correct estimation of the number of unobservable factors. The simulations are based on the DGP in Equation (45). Panels A-L contain the results assuming different combinations of parameters \( \rho, \beta \) and \( J \).
| Panel | Description | Results |
|-------|-------------|---------|
| A     | i.d. errors | (\rho = 0, \beta = 0, J = 0) |
| B     | serially correlated | (\rho = 0.7, \beta = 0, J = 0) |
| C     | cross-sectionally correlated | (\rho = 0, \beta = 0.2, J = 10) |
| D     | serially/cross-sectionally correlated | (\rho = 0.5, \beta = 0.2, J = 10) |

The table reports the percentages \(x\% / y\%\) of the replications that result in overestimation / underestimation of the number of factors using several criteria. The simulations are based on the DGP in Equation (45). Panels A-D contain the results assuming different combinations of parameters \(\rho, \beta\) and \(J\).
The table contains the probabilities of correct model selection estimated from the simulated unbalanced dataset when $r = 0$ (first row in each panel). For $r = 3$, the table reports the percentages $x\% / y\%$ of the replications that result in overestimation / underestimation of the number of factors (second row in each panel). The $(100 - x - y)\%$ of the replications is the probability of correct estimation of the number of unobservable factors. The simulations are based on the DGP in Equation (45) for unbalanced panels with $\min(T_i) = 60$. Panels A-L contain the results assuming different combinations of parameters $\rho$, $\beta$ and $J$. 

| Panel | Description | $Pr(\xi < 0 | M_1)$ | $Pr(\hat{k} > 3) / Pr(\hat{k} < 3)$ | $Pr(\xi < 0 | M_1)$ | $Pr(\hat{k} > 3) / Pr(\hat{k} < 3)$ | $Pr(\xi < 0 | M_1)$ | $Pr(\hat{k} > 3) / Pr(\hat{k} < 3)$ | $Pr(\xi < 0 | M_1)$ | $Pr(\hat{k} > 3) / Pr(\hat{k} < 3)$ |

The table contains the percentages \( x\%/y\% \) of the replications that result in overestimation / underestimation of the number of factors using several criteria. The simulations are based on the DGP in Equation (45) for unbalanced panels with \( \min(T_i) = 60 \). Panels A-D contain the results assuming different combinations of parameters \( \rho, \beta \) and \( J \).
Table 19: Monte Carlo replications of DGP (45) on unbalanced panels with min \( (T_i) = 120 \), one observable factor and \( r = 0 \) or 3 latent factors only

The table contains the probabilities of correct model selection estimated from the simulated unbalanced dataset when \( r = 0 \) (first row in each panel). For \( r = 3 \), the table reports the percentages \( x\% \)/\( y\% \) of the replications that result in overestimation / underestimation of the number of factors (second row in each panel). The \((100 - x - y)\% \) of the replications is the probability of correct estimation of the number of unobservable factors. The simulations are based on the DGP in Equation (45) for unbalanced panels with min \( (T_i) = 120 \). Panels A-L contain the results assuming different combinations of parameters \( \rho, \beta \) and \( J \).

Swiss Finance Institute

Swiss Finance Institute (SFI) is the national center for fundamental research, doctoral training, knowledge exchange, and continuing education in the fields of banking and finance. SFI’s mission is to grow knowledge capital for the Swiss financial marketplace. Created in 2006 as a public-private partnership, SFI is a common initiative of the Swiss finance industry, leading Swiss universities, and the Swiss Confederation.
