Neuropathologies include the deterioration and damage of the nervous system, especially neurons present in the brain, spinal cord and peripheral nervous system. Damage or alternations in neurons makes their structure and functionality abnormal. Every year over 90,000 people get affected by neurodegenerative diseases in the USA. Among all the neurological pathologies, the spinal cord injuries alone influence 10,000 people in the USA every year. Millions of cases of neurodegenerative pathologies are registered worldwide. Without proper treatment and cure to these cases, the toll for patients suffering from neurodegenerative disease is expected to reach at least 12 million in the USA 30 years from now (John, 2015).

Another aspect of neural pathologies includes peripheral nerve injury (PNI). Since mid 1980s, Food and Drug Administration have approved various natural and synthetic biomaterials based devices for repairing nerve defects arising from PNI. Worldwide, more than 8.5 million restricted activity days and approximately 5 million bed/disability days each year are results of PNIs (Belkas et al., 2004). The most unfortunate part of this is that all types of PNIs are not manageable via surgical intervention. The surgical procedures mainly neuroarthropy (direct suture repair without employing any grafted materials) can only be employed for shorter (< 5 mm) nerve gaps. Trials on repairing larger nerve defects by the similar neuroarthropy exert excessive tension on the suture line and offer poor surgical outcomes (Kehoe et al., 2012).

The present scenario necessitates an urgent need to discover new therapies and cure for neuropathological conditions.

It is well established that physical guidance of axons plays a vital role in nerve repair. Earlier in the 19th century, various kinds of materials were employed to provide physical guidance for the regeneration of injured nerves, namely, autologous nerve grafts, bone, metal tubes, and fat sheaths. During 1960s, Millesi et al. developed microsurgical techniques for aligning nerve fascicles precisely in the direct resection of nerve ends, with better functional recovery (Schmidt and Leach, 2003). Further, they also established the fact that nerve grafts placed between the damaged nerves makes the damaged nerve tension free and enhanced functional recovery. With the advancement in the medical innovations, various physical guidance conduits have been proposed with different biochemical stimuli for nerve regeneration in the course of time (John, 2015).

Polymers are mostly being used for nerve conduits due to their following characteristics: (i) soft and flexible nature similar to that of neural tissues; (ii) structural and functional similarity to the biomolecules existing in the extracellular matrix; (iii) biocompatibility and (iv) easy functionalization with essential proteins and growth factors for better performance. But, these polymeric scaffolds lack in mechanical strength and electrical conductivity, primary requisite for neural growth. Thus, the search was always on to have a suitable scaffold material with mechanical strength and electrical conductivity, along with other prerequisites for replacing neural tissue. Recently, neuroscientists are getting attracted towards conductive hybrid materials modulating the single neurons or neuronal networks being grown within the matrix, without any chance of CNT leaching or detachment from surface. Even if the implantation surgery avoids all the risks of detachment, post-implantation risks are also associated with these patterned substrates. Biological interactions with tissue interfaces offer the chance of the CNTs getting detached or leached out into the tissue fluid and ultimately to the blood stream, thus failing to retain the expected functionalities of the scaffold for neural regeneration. From the above mentioned breakthrough researches have some drawbacks, as noted below, which are needed to be taken care for fabricating a successful neural scaffold. The CNTs, being patterned on some substrates, are directly exposed on the surface of the scaffolds. The direct exposure of the CNTs presents a high probability of detachment from the substrate during implantation inside body. Even if the implantation surgery avoids all the risks of detachment, post-implantation risks are also associated with these patterned substrates. Biological interactions with tissue interfaces offer the chance of the CNTs getting detached or leached out into the tissue fluid and ultimately to the blood stream, thus failing to retain the expected functionalities of the scaffold for neural regeneration.

To overcome the above mentioned problem mentioned above leaching of CNTs from bare surface, the other serious problem with the above mentioned scaffolds were the substrate on which CNTs were patterned. The scaffolds, with patterned CNTs, are fabricated on various types of hard and non-polymeric substrates, e.g., glass, aluminium foils and silicon, using photolithography, chemical vapor deposition (CVD) and other micro-patterning techniques. These hard, non-polymeric, and non-biodegradable substrates would not be a good candidate for neural tissue engineering, due to their in vivo incompatibility with surrounding tissues. The over rigidity of these scaffolds causes nerve compression, imposing more deterioration to the damaged part. This is also the main drawback of some of the commercially available nerve guidance conduits.

Both of these was overcome by our group, in a recent study, through reinforcing the CNT patterns inside biocompatible soft polymer matrix (Gupta et al., 2015). The alignment of CNTs was maintained within the matrix, without any chance of CNT leaching and detachment from surface. The orientation of the CNTs can be clearly observed in Figures 1B and 1C. Figure 1B shows the CNTs oriented randomly in radial direction, while CNTs are well aligned in a particular direction in aligned scaffold (Figure 1C).
The alignment of CNTs inside chitosan matrix provided the anisotropic electrical conductivity, leading to the preferential alignment of neurons in the alignment direction. However, the beneficial effects of alignment of CNTs inside polymer matrix for neural tissue engineering have already been described, but it is rather difficult to get alignment of CNTs inside soft, biodegradable polymer substrates. The polymers generally cannot withstand the high temperature and strong chemical agents, required for most of the CNT alignment techniques. Therefore, the selection of the alignment method also became critical for our study. Finally the a.c. electric field application method was selected due to its simple and cost-effective nature to align the multi walled carbon nanotubes (MWCNTs) inside chitosan polymer matrix. This technique allows the easy and robust way to align the CNTs inside polymer-based scaffold, and not loosely attached to the surface. After characterizing the scaffold it was also confirmed that the scaffold offers all the expected cues/functions, particularly electrical conductivity. The alignment of the neurites and the cell bodies of HT-22 hippocampal neurons on alignedCNT-chitosan scaffold was studied and compared with the neurons grown on randomly oriented MWCNTs reinforced chitosan scaffold as well as chitosan scaffold alone. It was observed that the neurites do not prefer any direction for growth and show random orientation on both chitosan and chitosan-random MWCNT scaffolds (Figure 1D and 1E). However, the HT-22 rat hippocampal neurons on the chitosan-aligned MWCNT scaffolds (Figure 1F) behave distinctly different from other two scaffolds. The neurons, grown on the chitosan-aligned MWCNT scaffolds, show a favored direction of growth, which happens to be the alignment direction of nanotubes in the scaffolds. This directional neurite growth suggests the prospect of this scaffold for treating pathological conditions ranging from spinal cord injury to peripheral nerve repair, using transplanted cells. It was really a challenging task in itself, and there were no previous reports available for developing such kind of scaffolds. However, taking all the requisites into consideration, the study was designed to fabricate a modified polymer CNT scaffold that can simultaneously offer biological, mechanical, electrical, and topographical cues needed for neural tissue engineering.
