Abstract

We study a generalization of strongly regular graphs. We call a graph strongly walk-
regular if there is an $\ell > 1$ such that the number of walks of length $\ell$ from a vertex to
another vertex depends only on whether the two vertices are the same, adjacent, or not
adjacent. We will show that a strongly walk-regular graph must be an empty graph,
a complete graph, a strongly regular graph, a disjoint union of complete bipartite
graphs of the same size and isolated vertices, or a regular graph with four eigenvalues.
Graphs from the first three families in this list are indeed strongly $\ell$-walk-regular for all
$\ell$, whereas the graphs from the fourth family are $\ell$-walk-regular for every odd $\ell$. The
case of regular graphs with four eigenvalues is the most interesting (and complicated)
one. Such graphs cannot be strongly $\ell$-walk-regular for even $\ell$. We will characterize
the case that regular four-eigenvalue graphs are strongly $\ell$-walk-regular for every odd
$\ell$, in terms of the eigenvalues. There are several examples of infinite families of such
graphs. We will show that every other regular four-eigenvalue graph can be strongly
$\ell$-walk-regular for at most one $\ell$. There are several examples of infinite families of such
graphs that are strongly 3-walk-regular. It however remains open whether there are
any graphs that are strongly $\ell$-walk-regular for only one particular $\ell$ different from 3.

Keywords: Strongly regular graphs, Walks, Spectrum

1 Introduction

A strongly regular graph is a regular graph such that the number of common neigh-
bors of two distinct vertices depends only on whether these vertices are adjacent or not.
Strongly regular graphs are well-studied combinatorial and algebraic objects that arise in
the study of finite groups, codes, designs, and finite geometries (see the book by Brouwer
and Haemers [4], for example). Strongly regular graphs also have prominent general-
izations in the form of distance-regular graphs (see the book by Brouwer, Cohen, and

Neumaier [3], or the recent survey [8]) and association schemes (see the recent survey by Martin and Tanaka [13], for example).

Because the number of common neighbors of two vertices in a graph is the same as the number of walks of length two from one vertex to the other, we can generalize the concept of strongly regular graph by considering the number of walks of length — say — $\ell$ from one vertex to the other. Thus, we call a graph strongly walk-regular if there is an $\ell > 1$ such that the number of walks of length $\ell$ from a vertex to another vertex depends only on whether the two vertices are the same, adjacent, or not adjacent.

We remark that Godsil and McKay [10] introduced walk-regular graphs as those graphs for which the number of walks of length $\ell$ from a vertex to itself does not depend on the chosen vertex, but only on $\ell$. Rowlinson [14] characterized distance-regular graphs by the property that the number of walks of length $\ell$ between two vertices depends only on $\ell$ and the distance between the two vertices. Dalfó, Van Dam, Fiol, Garriga, and Gorissen [6] studied several versions of so-called almost distance-regularity by generalizing Rowlinson’s characterization. Let us emphasize that in these three papers [6, 10, 14], the mentioned properties should (typically) hold for all $\ell$, whereas here (in this paper) we require a certain property to hold for only one specific $\ell$.

At first sight, strongly walk-regular graphs also seem to be related to Kotzig’s conjecture about generalized friendship graphs. The friendship theorem states that if a graph has the property that every pair of vertices are connected by a unique path of length 2, then there is a vertex that is adjacent to every other vertex; the proof of this result is in “THE BOOK” [2, Ch. 34]. Kotzig [12] conjectured that for $\ell > 2$, there are no graphs with the property that every pair of (distinct) vertices are connected by a unique path of length $\ell$. According to Kostochka (see [2, p. 225]) this has been proven for $\ell \leq 33$. This conjecture and our problem are however very different. Not only do they differ because of the difference between paths and walks, but also in the fact that Kotzig only considers pairs of distinct vertices. We therefore leave to the reader the study of graphs with the property that the number of paths of length $\ell$ between two distinct vertices depends only on whether the two vertices are adjacent or not.

In this paper, we will show that a strongly walk-regular graph must be an empty graph, a complete graph, a strongly regular graph, a disjoint union of complete bipartite graphs of the same size and isolated vertices, or a regular graph with four eigenvalues. This conclusion can be drawn from Theorem 3.4 and Proposition 5.1. Graphs from the first three families in this list are indeed strongly $\ell$-walk-regular for all $\ell$, whereas the disjoint unions of complete bipartite graphs of the same size and isolated vertices are $\ell$-walk-regular for every odd $\ell$. The case of regular graphs with four eigenvalues, which is discussed in Section 4, is the most interesting (and complicated) one. Such graphs cannot be strongly $\ell$-walk-regular for even $\ell$. We will characterize the case that regular four-eigenvalue graphs are strongly $\ell$-walk-regular for every odd $\ell$, in terms of the eigenvalues. There are several examples of infinite families of such graphs. We will show that every other regular four-eigenvalue graph can be strongly $\ell$-walk-regular for at most one $\ell$. There are several examples of infinite families of such graphs that are strongly 3-walk-regular. It however remains open whether there are any graphs that are strongly $\ell$-walk-regular for only one particular $\ell$ different from 3.
2 The definition and some basic observations

We will now give the formal definition of the concept of a strongly walk-regular graph as mentioned in the introduction. For \( \ell > 1 \), a graph \( \Gamma \) is a strongly \( \ell \)-walk-regular graph with parameters \((\lambda_\ell, \mu_\ell, \nu_\ell)\) if there are \(\lambda_\ell\), \(\mu_\ell\), and \(\nu_\ell\) walks of length \(\ell\) between every two adjacent, every two non-adjacent, and every two identical vertices, respectively. So indeed, every strongly regular graph with parameters \((v, k, \lambda, \mu)\) is a strongly 2-walk-regular graph with parameters \((\lambda, \mu, k)\). We exclude the case \(\ell = 1\) because every graph would be a strongly 1-walk-regular graph with parameters \((1, 0, 0)\). Besides strongly regular graphs, also the empty and complete graphs give examples. Indeed, these graphs are clearly strongly \(\ell\)-walk-regular for every \(\ell\).

Let \(A\) be the adjacency matrix of \(\Gamma\). A crucial observation is that \(\Gamma\) is a strongly \(\ell\)-walk-regular graph if and only if \(A^\ell\) is in the span of \(A, I, J\). This follows from the following lemma that translates the combinatorial definition into an algebraic formulation. (For background on algebraic graph theory we refer to the book by Brouwer and Haemers [4].)

Lemma 2.1. Let \(\ell > 1\), and let \(\Gamma\) be a graph with adjacency matrix \(A\). Then \(\Gamma\) is a strongly \(\ell\)-walk-regular graph with parameters \((\lambda_\ell, \mu_\ell, \nu_\ell)\) if and only if \(A^\ell + (\mu_\ell - \lambda_\ell)A + (\mu_\ell - \nu_\ell)I = \mu_\ell J\).

Proof: This follows by observing that \((A^\ell)_{ij}\) counts the number of walks of length \(\ell\) between vertices \(i\) and \(j\).

For a strongly regular graph \(\Gamma\), its adjacency algebra (that is, the algebra spanned by all powers of \(A\)) equals \(\langle A, I, J \rangle\), so this implies that \(\Gamma\) is a strongly \(\ell\)-walk-regular graph for every \(\ell > 1\).

Proposition 2.2. Let \(\Gamma\) be a strongly regular graph. Then \(\Gamma\) is a strongly \(\ell\)-walk-regular graph with parameters \((\lambda_\ell, \mu_\ell, \nu_\ell)\) for every \(\ell > 1\) and some \(\lambda_\ell, \mu_\ell, \text{ and } \nu_\ell\).

At this point it seems appropriate to remark that Abreu, Funk, Labbate, and Napolitano [1] recently generalized the (strongly regular) Moore graphs with girth 5 by considering the equation \((k - 1)I + J - A^2)^m = A\). This is however a quite different equation in terms of \(A, I, \text{ and } J\) than the one we are considering.

Let us now make some more elementary observations that will help to see which other graphs can be strongly walk-regular.

Lemma 2.3. Let \(\ell > 1\), and let \(\Gamma\) be a strongly \(\ell\)-walk-regular graph with parameters \((\lambda_\ell, \mu_\ell, \nu_\ell)\) with \(\mu_\ell > 0\). Then \(\Gamma\) is regular and connected.

Proof: Because \(\mu_\ell > 0\), it follows from Lemma 2.1 that \(J\) can be expressed as a polynomial in \(A\). Hoffman [11] showed that this implies that \(\Gamma\) is regular (by observing that \(A\) commutes with \(J\)) and connected.

Note that also if \(\mu_\ell = 0\), the graph can be regular and connected. The complete bipartite graph \(K_{m,m}\) for example is strongly 3-walk-regular with parameters \((m^2, 0, 0)\). We will look further into the case \(\mu_\ell = 0\) in Section 5.
3 Connected regular graphs

We now first focus on the generic case and assume that the graphs are connected and regular.

Proposition 3.1. A connected \( k \)-regular graph \( \Gamma \) on \( v \) vertices is strongly \( \ell \)-walk-regular with parameters \((\lambda_\ell, \mu_\ell, \nu_\ell)\) if and only if all eigenvalues except \( k \) are roots of the equation

\[
x^\ell + (\mu_\ell - \lambda_\ell)x + \mu_\ell - \nu_\ell = 0
\]

and \( k \) satisfies the equation

\[
k^\ell + (\mu_\ell - \lambda_\ell)k + \mu_\ell - \nu_\ell = \mu_\ell v.
\]

Proof: If \( \Gamma \) is a strongly \( \ell \)-walk-regular graph with parameters \((\lambda_\ell, \mu_\ell, \nu_\ell)\), then \( A^\ell + (\mu_\ell - \lambda_\ell)A + (\mu_\ell - \nu_\ell)I = \mu_\ell J \). Every eigenvalue \( \theta \) unequal to \( k \) has an eigenvector that is orthogonal to the all-ones vector (the eigenvector for eigenvalue \( k \)), hence by multiplying the matrix equation with this eigenvector, we obtain the equation \( \theta^\ell + (\mu_\ell - \lambda_\ell)\theta + \mu_\ell - \nu_\ell = 0 \). By multiplying the matrix equation with the all-ones vector, the equation \( k^\ell + (\mu_\ell - \lambda_\ell)k + \mu_\ell - \nu_\ell = \mu_\ell v \) is derived.

On the other hand, consider the distinct eigenvalues \( k = \theta_0 > \theta_1 > \cdots > \theta_d \) and the Hoffman polynomial \( [11] \) \( h \) of \( \Gamma \). Here we normalize \( h \) such that it is monic, so that

\[
h(x) = \prod_{i=1}^{d} (x - \theta_i).
\]

(3.1)

In fact, \( h(A) = \frac{h(k)}{k} J \), because (3.1) implies that \( h(A) \) vanishes on each eigenspace of \( A \) corresponding to an eigenvalue unequal to \( k \), and thus it has rank 1 (because \( \Gamma \) is connected) with nontrivial eigenvalue \( h(k) \) having the all-ones vector as eigenvector.

Now, if the eigenvalue \( \theta_i \) satisfies the equation \( x^\ell + (\mu_\ell - \lambda_\ell)x + \mu_\ell - \nu_\ell = 0 \) for every \( i \neq 0 \), then the Hoffman polynomial divides \( x^\ell + (\mu_\ell - \lambda_\ell)x + \mu_\ell - \nu_\ell \). Because \( h(A) = \frac{h(k)}{k} J \) and \( p(A)J = p(k)J \) for every polynomial \( p \), this implies that \( A^\ell + (\mu_\ell - \lambda_\ell)A + (\mu_\ell - \nu_\ell)I = tJ \) for some \( t \). As before, this implies that \( k^\ell + (\mu_\ell - \lambda_\ell)k + \mu_\ell - \nu_\ell = \mu_\ell v \). But if \( k^\ell + (\mu_\ell - \lambda_\ell)k + \mu_\ell - \nu_\ell = \mu_\ell v \), then \( t = \mu_\ell \), and so \( \Gamma \) is a strongly \( \ell \)-walk-regular graph with parameters \((\lambda_\ell, \mu_\ell, \nu_\ell)\).

As a corollary, we obtain the following characterization that we will use later on.

Corollary 3.2. A connected regular graph is strongly \( \ell \)-walk-regular if and only if its Hoffman polynomial divides the polynomial \( x^\ell + ex + f \) for some \( e \) and \( f \).

Proof: One direction follows immediately from Proposition 3.1. To show the other direction, assume that the Hoffman polynomial divides the polynomial \( x^\ell + ex + f \) for some \( e \) and \( f \). Let \( v \) be the number of vertices and \( k \) the valency of the graph. Clearly, all eigenvalues besides \( k \) are roots of \( x^\ell + ex + f \). Now let \( \mu_\ell = \frac{1}{2}(k^\ell + ek + f), \lambda_\ell = \mu_\ell - e, \) and \( \nu_\ell = \mu_\ell - f \). Then Proposition 3.1 implies that the graph is \( \ell \)-walk-regular with parameters \((\lambda_\ell, \mu_\ell, \nu_\ell)\).

By bounding the number of real roots of \( x^\ell + ex + f \), we can bound the number of distinct eigenvalues of a strongly walk-regular graph.
Lemma 3.3. Let \( \ell > 1 \), and let \( p(x) = x^\ell + ex + f \) for some \( e \) and \( f \). Then \( p \) has at most three real roots. If \( \ell \) is even, then \( p \) has at most two real roots.

Proof: The derivative of \( p \) equals \( p'(x) = \ell x^{\ell - 1} + e \). So \( p' \) has at most two real roots if \( \ell \) is odd, and at most one real root if \( \ell \) is even. From this, the result follows.

We remark that if we know the sign of \( e = \mu \ell - \lambda \ell \) and \( f = \mu \ell - \nu \ell \), then some more information about the sign and number of real roots can be derived by using Descartes’ rule of signs (see [15]).

Because eigenvalues of graphs are real, the following result follows immediately from Corollary 3.2 and Lemma 3.3.

Theorem 3.4. Let \( \Gamma \) be a connected regular strongly \( \ell \)-walk-regular graph with \( \ell > 1 \). Then \( \Gamma \) has at most four distinct eigenvalues. Moreover, if \( \ell \) is even, then \( \Gamma \) has at most three distinct eigenvalues and hence \( \Gamma \) is either a complete graph or a strongly regular graph.

4 Graphs with four eigenvalues

Let us continue with the case of connected regular graphs. By Proposition 2.2 and Theorem 3.4, it remains to determine the strongly \( \ell \)-walk-regular graphs with four (distinct) eigenvalues for odd \( \ell \). Regular four-eigenvalue graphs have been studied by Van Dam and Spence [7, 9]. It is for example known that such graphs are walk-regular in the sense of Godsil and McKay [10]. Because strongly regular graphs are also walk-regular, it follows that every connected regular strongly walk-regular graph is indeed walk-regular. We remark that in Section 5, we will see some nonregular strongly walk-regular graphs, and these graphs cannot be walk-regular, because every walk-regular graph is regular.

Let \( \Gamma \) be a connected \( k \)-regular graph with four distinct eigenvalues \( k > \theta_1 > \theta_2 > \theta_3 \). Then by working out the Hoffman polynomial (3.1), it follows that

\[
A^3 - (\theta_1 + \theta_2 + \theta_3)A^2 + (\theta_1 \theta_2 + \theta_1 \theta_3 + \theta_2 \theta_3)A - \theta_1 \theta_2 \theta_3 I = tJ
\]

(4.1)

for some \( t \) (this \( t \) can be expressed in terms of the number of vertices and the eigenvalues, but this doesn’t play any role in the following). This proves the following.

Proposition 4.1. Let \( \Gamma \) be a connected regular graph with four distinct eigenvalues \( k > \theta_1 > \theta_2 > \theta_3 \). Then \( \Gamma \) is strongly 3-walk-regular if and only if \( \theta_1 + \theta_2 + \theta_3 = 0 \).

Proof: This follows from (4.1), and the fact that \( A^2 \) cannot be expressed in terms of \( A, I, J \), because otherwise \( \Gamma \) would be strongly regular, and thus have three distinct eigenvalues.

Several infinite families of examples of regular four-eigenvalue graphs with \( \theta_1 + \theta_2 + \theta_3 = 0 \) can be constructed using the methods of Van Dam [7]. Many, but certainly not all of these examples have integer eigenvalues only. For an example with noninteger eigenvalues, consider a conference graph, that is, a strongly regular graph with parameters \((4\mu + 1, 2\mu, \mu - 1, \mu)\). Its 3-clique extension (that is, every vertex is replaced by a clique of size 3, and vertices of different cliques are adjacent if and only if the original vertices are adjacent) has distinct eigenvalues \( k, \frac{3}{2}(-1 + \sqrt{4\mu + 1}) + 2, -1, \) and \( \frac{3}{2}(-1 - \sqrt{4\mu + 1}) + 2. \)
There are also some distance-regular graphs with diameter three that are strongly 3-walk-regular, such as the line graph of the incidence graph of the Fano plane, the Perkel graph, and the Hamming graph $H(3, 3)$.

Another family of examples is given by the complements of the graphs $K_{m,m} \oplus K_m$ (the sum [5] — also called Cartesian product — of a complete bipartite graph and a complete graph, see [7]). The distinct eigenvalues of the complement of $K_{m,m} \oplus K_m$ are $k = 2m(m - 1), m, 0,$ and $-m$. The zero eigenvalue simplifies (4.1) even further, and it implies that the graph is strongly $\ell$-walk-regular for every odd $\ell$.

**Proposition 4.2.** Let $\Gamma$ be a connected regular graph with four distinct eigenvalues $k > \theta_1 > \theta_2 > \theta_3$. If $\theta_2 = 0$ and $\theta_3 = -\theta_1$, then $\Gamma$ is strongly $\ell$-walk-regular for every odd $\ell$.

**Proof:** If $\theta_2 = 0$ and $\theta_3 = -\theta_1$, then the three eigenvalues $\theta_1, \theta_2,$ and $\theta_3$ are roots of the polynomial $x^\ell - \theta_1^{\ell-1}x$ for every odd $\ell$, so $\Gamma$ is $\ell$-walk-regular for every odd $\ell$ by Corollary 3.2.

On the other hand, if $\theta_2 \neq 0$ or $\theta_3 \neq -\theta_1$, then $\Gamma$ is $\ell$-walk-regular for at most one $\ell > 1$. In order to show this, we will use the following characterization.

**Proposition 4.3.** Let $\Gamma$ be a connected regular graph with four distinct eigenvalues $k > \theta_1 > \theta_2 > \theta_3$ and let $\ell \geq 3$. Then $\Gamma$ is strongly $\ell$-walk-regular if and only if

$$(\theta_2 - \theta_3)\theta_1^\ell + (\theta_3 - \theta_1)\theta_2^\ell + (\theta_1 - \theta_2)\theta_3^\ell = 0.$$  

(4.2)

**Proof:** As before, we will use that $\Gamma$ is strongly $\ell$-walk-regular if and only if the Hoffman polynomial $x^3 + ax^2 + bx + c$ divides a polynomial of the form $x^\ell + ex + f$. Let $x^\ell - 3 + \sum_{i=3}^{\ell-1} \alpha_i x^{\ell-1-i}$ be a putative quotient of these two polynomials (the unusual indexing will turn out to be convenient), and also define $\alpha_0 = \alpha_1 = 0$ and $\alpha_2 = 1$ (these can also be interpreted as coefficients of the same polynomial). Now consider the product of this polynomial and the Hoffman polynomial. The coefficients of $x^{\ell-1}$ down to $x^3$ in this product vanish if and only if the coefficients $\alpha_i$ satisfy the recurrence relation $\alpha_i + a\alpha_{i-1} + b\alpha_{i-2} + c\alpha_{i-3} = 0$ for $i = 3, 4, \ldots, \ell - 1$. The coefficient of $x^2$ in the product equals $a(\alpha_{\ell-1} + b\alpha_{\ell-2} + c\alpha_{\ell-3})$, so if we extend the recurrence by one more step by defining $\alpha_{\ell}$ such that $\alpha_{\ell} + a\alpha_{\ell-1} + b\alpha_{\ell-2} + c\alpha_{\ell-3} = 0$, then it follows that $\Gamma$ is strongly $\ell$-walk-regular if and only if $\alpha_{\ell} = 0$.

Now all that is left is to find the solution for the recurrence relation. But the characteristic polynomial of this recurrence relation is the Hoffman polynomial that has distinct roots $\theta_1, \theta_2,$ and $\theta_3$. Therefore $\alpha_i = \beta_1 \theta_1^i + \beta_2 \theta_2^i + \beta_3 \theta_3^i$ for $i = 0, 1, \ldots, \ell$ for some $\beta_1, \beta_2$, and $\beta_3$. Given that $\alpha_0 = \alpha_1 = 0$, and $\alpha_2 = 1$, it follows that

$$-(\theta_1 - \theta_2)(\theta_2 - \theta_3)(\theta_3 - \theta_1)\alpha_i = (\theta_2 - \theta_3)\theta_1^i + (\theta_3 - \theta_1)\theta_2^i + (\theta_1 - \theta_2)\theta_3^i,$$

which finishes the proof.

**Theorem 4.4.** Let $\Gamma$ be a connected regular graph with four distinct eigenvalues $k > \theta_1 > \theta_2 > \theta_3$. If $\theta_2 \neq 0$ or $\theta_3 \neq -\theta_1$, then there is at most one $\ell > 1$ such that $\Gamma$ is strongly $\ell$-walk-regular.
Proof: Suppose on the contrary that \( \Gamma \) is strongly \( \ell \)-walk-regular and strongly \( m \)-walk-regular with \( m > \ell > 1 \). Note that (4.2) implies that \( \theta_2 \neq 0 \) if and only if \( \theta_3 \neq -\theta_1 \), so we may assume both. Similarly, we may assume that \( \theta_3 \neq -\theta_2 \). A final assumption that we will make is that \( \theta_1 > |\theta_2| \) and \( \theta_1 > |\theta_3| \). We can do this without loss of generality because if we replace the eigenvalues \( \theta_1, \theta_2, \) and \( \theta_3 \) by their opposites, then (4.2) still holds (and we will not make use of other specific properties of the eigenvalues).

Note that (4.2) trivially holds for \( \ell = 1 \), so if we define the matrix \( M \) by

\[
M = \begin{bmatrix}
\theta_1 & \theta_2 & \theta_3 \\
\theta_1^\ell & \theta_2^\ell & \theta_3^\ell \\
\theta_1^m & \theta_2^m & \theta_3^m
\end{bmatrix},
\]

then the equation \( Mx = 0 \) has a nontrivial solution, and so \( \det M = 0 \). Because \( \theta_1 \theta_2 \theta_3 \neq 0 \), this is equivalent to \( (\theta_2^{\ell-1} - \theta_1^{\ell-1})(\theta_3^{m-1} - \theta_1^{m-1}) = (\theta_3^{\ell-1} - \theta_1^{\ell-1})(\theta_2^{m-1} - \theta_1^{m-1}) \). Now we define the function \( f \) by \( f(x) = \theta_2^{m-1}x^{m-1} - \theta_1^{m-1}x^{m-1} \), so then \( f(\theta_2) = f(\theta_3) \) (note that \( \ell \) and \( m \) are odd). We claim however that \( f \) is strictly increasing on the interval \((0, \theta_1)\), which will give the required contradiction. To prove the claim, consider the function \( g \) defined by \( g(x) = f'(x)(\theta_2^{\ell-1} - x^{\ell-1})^2/x^{\ell-2} \). Then it is straightforward to show that \( g(x) = (m-\ell)x^{m-1}-(m-1)\theta_1^{m-1}x^{m-1}+x^{m-1}+x^{m-1} \) and \( g'(x) = (m-1)(m-\ell)x^{m-2}x^{m-1} \). So \( g(\theta_1) = 0 \) and \( g'(x) < 0 \) if \( 0 < x < \theta_1 \). Therefore \( g(x) > 0 \) if \( 0 < x < \theta_1 \), and this implies indeed that \( f \) is strictly increasing on \((0, \theta_1)\).

We tried to find (relevant) nonzero solutions to (4.2) for some small \( \ell > 3 \). We could not find integer solutions, but we did find some solutions for \( \ell = 5 \) with two conjugate noninteger eigenvalues and one integer eigenvalue (for example \( 5, \frac{1}{2}(-3+\sqrt{281}), \frac{1}{2}(-3-\sqrt{281}) \)). We however have no clue whether there are any regular four-eigenvalue graphs with these particular eigenvalues (note that there is still freedom in “choosing” the number of vertices and the valency). It thus remains open whether there are strongly \( \ell \)-walk-regular graphs with \( \ell > 3 \) that are not strongly \( m \)-walk-regular for all odd \( m \neq \ell \).

We note that given \( \ell \), and two of the three eigenvalues, say \( \theta_2 \) and \( \theta_3 \), one can consider (4.2) as a polynomial equation in \( \theta_1 \), and this has two trivial roots \( \theta_2 \) and \( \theta_3 \). By using again Lemma 3.3, it follows that there can be no other real root for \( \ell \) even (which confirms part of Theorem 3.4), and one other real root for \( \ell \) odd. In other words, for a given odd \( \ell \), and given \( \theta_2 \) and \( \theta_3 \), there is one real solution to (4.2) for \( \theta_1 \) that is different from \( \theta_2 \) and \( \theta_3 \). But typically this solution seems to be unfit as an eigenvalue of a graph.

5 The exceptional case

What remains in this paper is to classify the strongly \( \ell \)-walk-regular graphs with parameters \((\lambda_\ell, 0, \nu_\ell)\), that is, those with \( \mu_\ell = 0 \). In this case, we have the equation \( A^\ell - \lambda_\ell A - \nu_\ell I = O \) (by Lemma 2.1). Thus, \( \Gamma \) is strongly \( \ell \)-walk-regular graph with parameters \((\lambda_\ell, 0, \nu_\ell)\) if and only if every eigenvalue of \( \Gamma \) is a root of the polynomial \( x^\ell - \lambda_\ell x - \nu_\ell \). We again use Lemma 3.3 to obtain the following classification.

**Proposition 5.1.** Let \( \ell > 1 \) and let \( \Gamma \) be a nonempty strongly \( \ell \)-walk-regular graph with parameters \((\lambda_\ell, 0, \nu_\ell)\). Then either \( \Gamma \) is a disjoint union of complete graphs of the same
order, or $\ell$ is odd and $\Gamma$ is a disjoint union of complete bipartite graphs of the same size and isolated vertices.

Proof: First, let $\ell$ be even. Then by Lemma 3.3 the polynomial $x^\ell - \lambda \ell x - \nu_\ell$ has at most two real roots, so $\Gamma$ has at most two distinct eigenvalues. This implies that $\Gamma$ is the disjoint union of complete graphs of the same order (number of vertices) \cite[Thm. 6.4]{5}.

Next, let $\ell$ be odd. In this case, it follows that $\Gamma$ has at most three distinct eigenvalues. Let us assume that $\Gamma$ is not a disjoint union of complete graphs of the same order, then $\Gamma$ has three distinct eigenvalues. Consider first the case that $\nu_\ell = 0$. Then the eigenvalues of $\Gamma$ are $\theta$, 0, and $-\theta$, for some $\theta$. This implies that $\Gamma$ is indeed a disjoint union of complete bipartite graphs of the same size (number of edges) and possibly some isolated vertices (cf. \cite[Thm. 6.5]{5}).

Finally, we consider the case where $\Gamma$ has three distinct eigenvalues and $\nu_\ell > 0$ (and $\ell$ is odd). Now 0 is not an eigenvalue, and we will show that this gives a contradiction. Also, in this case $\Gamma$ cannot have two complete graphs of different orders as components (because these would give different values for $\nu_\ell$). We assumed that $\Gamma$ is not a disjoint union of complete graphs of the same order, so there is a component $C$ of $\Gamma$ that is not a complete graph. This component also has at most three eigenvalues, and so it has diameter at most 2. Consider vertices $u$ and $v$ in $C$ that are not adjacent. Then $u$ and $v$ are at distance two, and so there is a walk of length 3, and hence of length $\ell$, between $v$ and each of the neighbors of $u$. Because $\mu_\ell = 0$, this implies that $v$ is adjacent to all neighbors of $u$. Thus, every nonneighbor of $u$ (including $u$ itself) is adjacent to every neighbor of $u$. It also follows easily that there are no edges among the neighbors of $u$ and that there are no edges among the nonneighbors of $u$ (otherwise there would be a walk of length 3 between $u$ and a nonneighbor of $u$). Therefore $C$ is a complete bipartite graph, which gives the required contradiction.

Note that the disjoint union of complete graphs $K_n$ is strongly regular, so indeed it is strongly $\ell$-walk-regular for every $\ell$ (by Proposition 2.2). If $\Gamma$ is a disjoint union of complete bipartite graphs, all of which have the same number of edges, and possibly some isolated vertices, then indeed $\Gamma$ is strongly $\ell$-walk-regular for every odd $\ell$. Note finally that the disjoint union of complete graphs $K_2$ and $K_1$ (of different orders) is a special case of a disjoint union of complete bipartite graphs and isolated vertices, which is why we split the cases $\nu_\ell = 0$ and $\nu_\ell > 0$ in the above proof.
