Background: To determine the natural progression of conservatively treated rotator cuff tears, we evaluated changes in radiologic and clinical parameters in patients whose recalcitrant tears were neglected after conservative treatment.

Methods: A total of 73 patients with recalcitrant rotator cuff tears in spite of conservative treatment were included in this study. We measured changes in tear size and in the extent of fatty infiltration of the rotator cuff by comparing the initial and final follow-up magnetic resonance imagings (MRIs). To determine factors influencing the change in tear size, we collected the medical history of patients taken at the time of initial admission.

Results: The average follow-up period was 20.1 months, and the average increase in tear size across this period was 6.2 mm. In terms of steroid injection, we found that the increases in tear size of the steroid injection group (p=0.049) and of the sub-group that had received more than three steroid injections (p=0.010) were significantly greater than that of the non-steroid injection group.

Conclusions: We found that the increase in cuff tear size was on average 6.2 mm across the follow-up period, indicating that neglecting cuff tears may cause them to progress into more severe tears. We also observed that a history of steroid injection might be a possible risk factor for a worse prognosis of cuff tears. Therefore, we suggest that patients with rotator cuff tears and a history of steroid injection are recommended aggressive modes of treatment such as surgery.

Key Words: Rotator cuff injury; Steroid; Injection; Intra-articular

Introduction

Rotator cuff tears are one of the most common tendinous injuries in adults.¹,² Muscle fibers of the rotator cuff become torn because mechanistically they receive persistent tension, which in a rotator cuff tear causes even greater contraction-induced damage. The prognosis of rotator cuff arthropathies resulting from mechanistic reasons alone has been shown to be difficult to predict.³,⁴ On one hand, the symptoms of 60% of patients with full-thickness cuff tears were found to be improved after conservative treatment.⁵ On the other hand, 18 of 50 patients with asymptomatic cuff tears were found to have significantly progressed symptoms and exacerbated cuff tears by the end of a 3-year follow-up.⁶

Although it is clear the conservative treatment of rotator cuff tears is associated with resolution of pain and improvement in range of motion, the natural history of patients who receive non-surgical approaches to treatment remains unclear. The factors thought to influence the natural history of rotator cuff tears, which may also be important for their treatment, are still controversial among orthopedic surgeons.

Radiological tests such as magnetic resonance imaging (MRI) have been shown to be most accurate for the diagnosis of rotator cuff tears. It has been reported that the accuracy of MRI in diagnosing full-thickness rotator cuff tears is greater than 95%. In this study, we analyzed MRI findings of patients who were initially hospitalized for shoulder pain, which was diagnosed as a rotator cuff tear, were treated conservatively, but were later re-hospitalized for recalcitrant tears that were neglected without appropriate treatment. We investigated the natural history of the rotator cuff tears in terms of the change in cuff tear size, as measured on patients’ MRI scans, and of clinical parameters. In addition, we investigated putative factors at the time of initial admission that could be involved in the progression of cuff tear size.

Methods

We enrolled 73 patients who were hospitalized for shoulder pain and whose condition was diagnosed as a rotator cuff tear through diagnostic MRI. The patients’ condition had been either neglected or conservatively treated initially but were neglected without further treatment because the cuff tears were recalcitrant despite treatment. We conducted a multicenter retrospective study involving ten hospitals across Korea to investigate the change in tear size over time. We analyze putative patient-related factors at the time of initial admission, for which we asked patients for information, such as history of trauma, steroid injections, and shoulder use.

We divided the tears into either partial or full-thickness tears on the basis of tear depth. The extent of fatty infiltration was evaluated on oblique sagittal MRI sections and categorized following the Goutallier classification system at both the initial and final follow-up examinations. Partial rotator cuff tears were evaluated on oblique coronal MRI sections, and complete rotator cuff tears were evaluated on oblique coronal MRI sections. We measured the average change in tear size and in the extent of fatty infiltration between the initial and final follow-up examinations in terms of the extent of tendon retraction. Two orthopedic surgeons each analyzed the MRI scans, and the intraclass correlation coefficient was used to determine the interobserver reliability.

We measured change in the clinical parameters—pain and shoulder function—denoted as the difference in visual analogue scale (VAS) score for pain and in the American Shoulder and Elbow Surgeons (ASES) score, respectively, between the initial and final follow-up examinations. The level of shoulder pain was determined on the basis of a 3-item criteria (forward elevation, <120°; internal rotation, <13; or external rotation at side, <20°). We used either the chi-square or the Fisher exact test to examine the correlation between two categorical variables and the Pearson correlation coefficient, between two continuous variables. The paired t-test was used to perform a quantitative analysis between two independent variables, and ANOVA was used for more than three independent variables. Statistical significance was considered as a p-value below 0.05.

Results

Of the total study participants, 43.8% were male and 56.2% were female (32 vs. 41 patients). The age of the patients was on average 59.8 years and showed a large range (range, 34–83 years). The proportions of patients with shoulder pain in the absence and in the presence of a history of trauma were 69.9% (51/73 patients) and 30.1% (22/73 patients), respectively. In the latter group, 19 patients had had light trauma and only 3, severe trauma. All patients received a diagnosis of a rotator cuff tear through diagnostic MRI. The proportion of patients with an occupation involving manual labor was 40.0% (27 patients). Those engaged in sports activities demanding substantial shoulder use was 24.6% of the study population. The proportion of patients who had received at least one steroid injection at the initial admission was 35.6% (26 patients), from which 20.6% (15 patients) had received more than three steroid injections (Table 1).

From initial diagnosis, patients had either not received any sort of treatment or had received various conservative treatments between one month and six year to no avail. The patients were re-hospitalized on average 20.1 months of the initial admission because of recalcitrant and/or exacerbated symptoms. We conducted MRI examinations again at the second admission. Between the initial and final follow-up examinations, we found that the average VAS score for pain had increased from 5.7 to 6.3 and that the ASES score had decreased from 44.9 to 42.4. By the final follow-up, the number of patients with shoulder stiffness and with fatty degeneration increased from 11 to 16 pa-

Table 1. Patient Demographics

| Variable                          | Value          |
|----------------------------------|----------------|
| Total patient                    | 73             |
| Sex (male/female)                | 32/41          |
| Age (male/female) (yr)           | 59.8 (34–75)/59.9 (48–83) |
| Steroid injection history        | 7/4/15         |
| (once/twice/≥3 times)            |                |
| Trauma history (minor/major/none)| 19/3/51        |

Values are presented as number only or median (range).
patients and from 43 (58.9%) to 61 patients (83.6%), respectively. Across the same period, we found that the average Goutallier grade denoting the level of fatty degeneration increased from 0 to 2 (Table 2).

The interobserver reliability for the measurements of the change in tear size was 0.88 mm, revealing substantial reliability. The average increase in tear size depicted on oblique coronal MRI sections between the initial and final follow-up examinations was 6.2 mm (from 10.4 to 16.6 mm). The largest increase in tear size was 32.1 mm (Fig. 1). The number of muscles involved in the tear at the final follow-up was greater in ten patients than before (i.e., from an isolated supraspinatus tendon tear to a combined supraspinatus and subscapularis tendon tear). We also observed that the tear depth was altered in 24 patients (from a partial thickness tear to a full-thickness tear). By gender, the average increase in tear size was 5.66 mm in female patients and 6.85 mm in male patients, but no gender difference was observed. A statistically significant difference was not observed even when we compared by whether or not patient had a labor-heavy occupation ($p=0.986$). Although the group that played sports activities demanding substantial shoulder movement had a larger increase in tear size than those that did not, the difference was not significant ($p=0.083$).

We found that patients who had a history of steroid injection at initial admission had significantly larger change in tear size than those without ($p=0.049$). This association was even more prominent in patients who had a history of three or more steroid injections at initial admission ($p=0.010$) (Table 3). The percentage of patients who went on to receive surgical treatment after the final follow-up was 95.9% (70/73), two of whom underwent shoulder arthroplasty.

**Discussion**

The natural history of rotator cuff tears remains controversial and is currently being studied by several groups. On one hand, Mall et al. reported that across a 2-year or longer follow-up full-thickness rotator cuff tears increased by 5 mm in 18% of patients.
and partial tears progressed into full-thickness tears in 40% of patients (n=195). On the other hand, Fucentese et al.\(^\text{11}\) reported that the increase in tear size observed on magnetic resonance arthrograms after a 3.5-year follow-up was not statistically significant.

The subjects of our study were patients who had received conservative treatment for shoulder pain that had been diagnosed as a rotator cuff tear through diagnostic MRI. Using patients’ MRI sections, we measured the change in tear size over time and determined factors that may influence these changes.

There has been substantial research on tear size of symptomatic rotator cuff tears, giving varied results. Previous research has shown that the tear size of full-thickness tears of supraspinatus muscles did not increase with statistical significance across a 3.5-year follow-up in patients younger than 65 years.\(^\text{12}\) Conversely, full-thickness tears in 39% of patients were found to have significantly increased by 5 mm on ultrasound findings over a 5-year follow-up.\(^\text{13}\) Yamanaka and Matsumoto\(^\text{14}\) also reported that 80% of patients with partial cuff tears conservatively treated showed an increase in tear size and progression to a full-thickness tear (as determined on joint arthrography) over a 2-year follow-up. Safran et al.\(^\text{15}\) reported a 5-mm increase in tear size over a 2- to 3-year period in over half their patients who were aged less than 60 years old and treated conservatively for a rotator cuff tear. With respect to etiology of exacerbated tears, Iannotti and Williams\(^\text{16}\) have suggested that tears become worse over time because substances that help regeneration at the rotator cuff tear site are washed away by the synovial fluid. In our study, the average follow-up period was 20.1 months across which we observed an average 6.2-mm increase in cuff tear size.

Numerous studies have investigated factors influencing the cause of exacerbated or recalcitrant cuff tears. Dean et al.\(^\text{17}\) reported that steroid injections impair revascularization and production of hypoxia-inducible factor-1α, which are both involved in the repair response, thereby delaying rotator cuff recovery. Similarly, Mikolyzk et al.\(^\text{18}\) demonstrated that steroids weaken the strength of cuff muscles. Our finding that a history of steroid injection at initial admission is associated with a statistically significant increase in tear size is consistent with these previously reported findings. The same was true for patients who received at least three steroid injections at initial admission. Therefore, we can conclude that conservative treatment in patients with a history of steroid injection may not be as effective as when the same treatment is performed in patients who have no history of steroid injections.

Additionally, we found that the change in tear size did not significantly differ between those who were engaged in sports activities requiring substantial shoulder movement and those who were not, although the former group did tend to have a larger change. Thus, patients with rotator cuff tears should be warned that engaging in too much exercise requiring the shoulders could lead to worse prognosis of the cuff tears and that returning to pre-injury level of sports as soon as symptoms alleviate may necessitate surgical treatment later on.

A few studies have shown that conservative treatment of cuff tears improves arm function and alleviates pain at short-to-mid-term follow-ups. However, other studies have shown that conservative treatment was associated with low satisfaction levels at long-term follow-ups (more than 6 years).\(^\text{19,20}\) Many patients with recalcitrant cuff tears in spite of conservative treatment are re-hospitalized within a few years because of recurrent symptoms. They are found to have exacerbated tears and a significantly lowered rate of complete and successful cuff repairs.\(^\text{21,22}\)

In our study, we found that over 96% of patients who were re-hospitalized for recalcitrant tears received surgical treatment. Two patients had severely degenerated tears and therefore underwent arthroplasty. Rotator cuff tears may be neglected despite its diagnosis because they are asymptomatic or be treated conservatively and lead to only a temporary relief of symptoms. But when patients return to unrestrained level of activities without completely repairing the rotator cuff tear, we can predict that if symptoms recur patients would most likely require surgical treatment.

There are several limitations that restrict the significance of our study. As a retrospective study with a small study population, the statistical power of this study is limited. Only patients whose symptoms exacerbated or recurred were enrolled in this study, while those whose symptoms had resolved or patients who did not return to our hospital for various reasons (went to a different hospital or died) were not included; therefore, the study design lends itself to selective bias. These limitations should be addressed in subsequent studies, and a large-scale, randomized controlled prospective study is needed. Yet despite these limitations, our study is notable in that it has investigated the natural history of patients with symptomatic rotator cuff tears and uncovered new risk factors of poor prognosis or progression of cuff tear size.

**Conclusion**

We found that in the absence of appropriate treatment of rotator cuff tears, tear size increased on average 6.2-mm over an average 20.1-month period. We found that a history of steroid injection may be a risk factor for poor prognosis whilst a history of more than three steroid injections was a much stronger indicator of progression of rotator cuff tears. Thus, on the basis of our findings, we recommend that when such patients are met at the clinic they should be informed that conservative treatment may be ineffective and be strongly advised to receive more aggressive modes of treatment.
