ABSTRACT. Intersection homology is a topological invariant which detects finer information in a space than ordinary homology. Using ideas from classical simple homotopy theory, we construct local combinatorial transformations on simplicial complexes under which intersection homology remains invariant. In particular, we obtain the notions of stratified formal deformations and stratified spines of a complex, leading to reductions of complexes prior to computation of intersection homology. We implemented the algorithmic execution of such transformations, as well as the calculation of intersection homology, and apply these algorithms to investigate the intersection homology of stratified spines in Vietoris-Rips type complexes associated to point sets sampled near given, possibly singular, spaces.

1. INTRODUCTION

In [4], Bendich and Harer proposed the use of intersection homology, a finer invariant than ordinary homology, in the topological analysis of large data sets. In particular, they defined persistent intersection homology and described its algorithmic computation. Bendich and Harer conclude by asking whether in addition to persistence considerations and the selection criteria imposed by intersection homology, other simplex removal processes might be conducive to a finer understanding of large data sets. In the present paper, we adapt ideas from classical simple homotopy theory ([22], [10]), due to J. H. C. Whitehead, to the stratified setting in order to construct local combinatorial operations on a simplicial complex under which intersection homology provably remains invariant. These operations lead in particular to a class of stratified spines of a complex that are algorithmically computable, generally not
homeomorphic to each other, yet possess isomorphic intersection homology groups. Spines are well-known to carry deep information on the topological complexity of spaces, sometimes even allowing for classification results, see e.g. \([17]\). Carrying over algorithmic simplicial reduction processes to filtered and stratified settings is in line with the general objective in topological data science of finding ways to reduce the size of complexes (while preserving topological invariants), before computing homology. Zomorodian \([23]\), for example, underscores the advantage of prior reduction by citing the supercubical complexity in the size of the complex of classical matrix reduction algorithms for computing homology over the integers, and the quadratic space and cubic time complexity of Gaussian elimination over field coefficients.

The ordinary homology of a topological space is invariant under homotopy equivalences. If the space is a closed oriented manifold, then the ordinary homology satisfies in addition Poincaré duality, relating the groups in complementary dimensions. The homotopy invariance is of course a fundamental general pillar of the theory, but allows in particular for applications of homology in data science, since the simplicial complexes generated from data point clouds are usually only homotopy equivalent to an underlying space whose structure one hopes to detect. General homotopy equivalences in high dimensions are very complicated, both conceptually and algorithmically. This was realized early on in the development of topology and prompted research on more combinatorial models of homotopy equivalences. In his landmark paper \([22]\), J. H. C. Whitehead introduced the notion of simple homotopy equivalence, which for simplicial complexes can be described entirely combinatorially in terms of local operations: elementary simplicial collapses and expansions. This notion together with Whitehead’s torsion became very influential in high dimensional manifold topology, yielding such results as the \(s\)-cobordism theorem.

Poincaré duality on the other hand is the source of numerous invariants that play important roles in understanding and classifying manifolds even within their simple homotopy type. However, in real world applications, spaces often possess strata of non-manifold, i.e. singular, points. Simple examples show that the presence of such singularities generally invalidates Poincaré duality. Several solutions to this problem exist: Goresky-MacPherson’s intersection homology \([13]\), \([14]\), Cheeger’s \(L^2\)-cohomology \([6]\), \([7]\), \([8]\) and the theory of intersection spaces, \([2]\), due to the first named author. The present paper is concerned only with intersection homology.

Now, contrary to ordinary homology, intersection homology is not invariant under arbitrary homotopy equivalences, even when these are simple in Whitehead’s sense. On the other hand, stratum preserving homotopy equivalences will not alter intersection homology, even when they are not simple. A natural question is thus: Do there exist local simplicial moves that are akin to Whitehead’s, but do preserve given strata and intersection homology? We report here on the discovery of such moves; we call them stratified collapses and expansions. In the manifold situation with only one stratum, these coincide with Whitehead’s operations. The stratified collapses and expansions defined here may ultimately lead to a concept of stratified simple homotopy type, which we shall not fully develop in the present paper. Classically, finite sequences of elementary collapses and expansions are called formal deformations. We thus define stratified formal deformations as finite sequences of stratified collapses and expansions. Our central theoretical result, Theorem \([6.2]\), states that stratified formal deformations (assumed to preserve formal codimensions of strata) are stratified homotopy equivalences in the classical sense. An immediate corollary is that intersection homology remains invariant under such stratified formal deformations (Corollary \([6.4]\)). These results can be reinterpreted as giving conditions under which the intersection homology of a given space can be computed
directly from a Vietoris-Rips type complex of data points near the space (Corollary 6.5), but the conditions may be hard to check a priori.

Whitehead’s theory implies in particular the concept of a spine of a complex. Intersection homology satisfies Poincaré duality for spaces that are so-called pseudomanifolds. These allow for a notion of orientability. It is an easy observation (see Lemma 4.1) that if in a given complex one looks for pseudomanifolds obtainable by simplicial collapses, then one must seek them among the spines of that complex. Therefore, and for reasons mentioned earlier, spines constitute a particularly important class of subcomplexes. Our stratified simple homotopy transformations lead to a notion of a stratified spine of a stratified complex. In general, a given complex will have nonhomeomorphic stratified spines, but our main theorem implies that any two (codimension preserving) stratified spines have isomorphic intersection homology groups. Of course a given (ordinary, i.e. unstratified) expansion of a pseudomanifold $X$ may not possess a stratified spine which is homeomorphic to $X$, or which even just has the same intersection homology as $X$ (though it trivially always contains an ordinary spine with that property, namely $X$ itself). In such cases, different methods are required to determine the intersection homology of $X$ from the expansion.

We have implemented the execution of stratified collapses, computation of stratified spines, and the calculation of intersection homology with $\mathbb{Z}/2\mathbb{Z}$-coefficients in Python, and use this implementation to provide various examples of stratified spines, and their intersection homology, of Delaunay-Vietoris-Rips type complexes associated to data points sampled near various singular spaces. From the computational point of view, the idea of determining a spine prior to computing homology has the advantage of leading to smaller matrices representing chain complex boundary operators. Vietoris-Rips and similar complexes generally contain a vast number of topologically insignificant simplices, and spines tend to reduce that number substantially. In particular, the dimension of the spine will often be lower than the dimension of the original complex. This also means that in practice the “true” codimension of a singular point can be better estimated from its geometric codimension in the spine than from its geometric codimension in the original complex.

Interesting questions not treated in this paper concern sampling methods and stratification learning. The question, for example, of describing conditions on point distributions near a singular space $X$ that will ensure that the associated Čech- or Vietoris-Rips-type complex contains stratified spines homeomorphic (say) to $X$ requires quite different methods. Throughout the paper we assume, as do Bendich and Harer in [4], that for each point it is known whether to deem it regular or singular. See however [20] for some suggestions of heuristics.

The paper is organized as follows: Section 2 recalls basic material on simplicial complexes and Whitehead’s classical simple homotopy theory, particularly the notions of simplicial collapses, expansions and spines. Intersection homology is reviewed in Section 3. We define it in a rather general setting of filtered spaces and do not limit ourselves to pseudomanifolds. Perversity functions are also allowed to be more general than in the classical papers of Goresky and MacPherson. Section 4 develops the central notions of stratified collapses and expansions, as well as stratified spines. Several results are proven that clarify the effect of commuting these operations; these results are used in the algorithm design. To relate formal combinatorial collapses to continuous deformations, we introduce in Section 5 particular representatives of stratified homotopy equivalences called freely orthogonal deformation retractions. The main theoretical results are contained in Section 6 while Section 7 discusses algorithm design and miscellaneous aspects of our computer implementation. We conclude with exemplary executions of these algorithms on various sampled point clouds in Section 8.
Acknowledgements: We would like to thank Bastian Rieck for early discussions on ordinary spines and computations using his Aleph-package.

2. Simplicial Collapses, Expansions and Spines

We use the term simplicial complex in the sense of [19, §3, p. 15]; see also [21, 2.27, p. 26]. Thus a simplicial complex is a set of finite nonempty sets such that if \( s \in K \), then every nonempty subset (“face”) of \( s \) is also in \( K \). The elements \( s \in K \) of a simplicial complex \( K \) are referred to as its (closed) simplices. The dimension of a simplex \( s \) is its cardinality minus 1. The 0-dimensional simplices of \( K \) will be called vertices. The set of vertices of \( K \) will be denoted \( K_0 \). Note that a simplex is thus uniquely determined by its vertices. For \( s, t \in K \), it will be convenient to write \( t \leq s \) if \( t \) is a face of \( s \), and \( t < s \) if \( t \) is a proper face of \( s \). The associated polyhedron (or geometric realization) of a simplicial complex \( K \) is a topological space denoted by \( |K| \). Thus we are careful to distinguish between a simplicial complex \( K \) and the topological space \( |K| \). If we wish to distinguish denotationally regarding a simplex \( s \) as an element of \( K \) or as a closed subset of \( |K| \) (given by the convex hull of its vertices), then we shall write \( |s| \) for the latter. Points \( x \in |K| \) can be described using barycentric coordinates: there are unique numbers \( x_u \in [0,1] \) for every vertex \( u \in K_0 \) such that

\[
x = \sum_{u \in K_0} x_u u, \quad \text{and} \quad \sum_{u \in K_0} x_u = 1.
\]

Note that our simplicial complexes are abstract and do not come equipped with an embedding into some Euclidean space. This is in line with the intended applications in topological data science, where simplicial complexes such as the Čech complex or Vietoris-Rips complex of a data point cloud are given as abstract complexes without a preferred embedding in a Euclidean space.

Definition 2.1. A simplex in \( K \) is called principal (in \( K \)), if it is not a proper face of any simplex in \( K \).

Note that if \( K \) is finite-dimensional, then all top-dimensional simplices are principal, but there may well be principal simplices that are not top-dimensional.

Definition 2.2. A simplex \( s \) in \( K \) is called free (in \( K \)) if

1. \( s \) is a proper face of a principal simplex \( p \) in \( K \), and
2. \( s \) is not a proper face of any simplex in \( K \) other than \( p \).

Thus if \( s \) is a free simplex, then it is the proper face of precisely one simplex \( p \in K \), and this \( p \) must be principal. We may hence put

\[
\text{Princ}_K(s) := p.
\]

If \( K \) is understood, then we shall also simply write \( \text{Princ}(s) \).

Lemma 2.3. If \( s \in K \) is free, then \( \dim \text{Princ}(s) - \dim s = 1 \).

Proof. Since \( s < \text{Princ}(s) \), we have the bound \( \dim s \leq \dim \text{Princ}(s) - 1 \). Suppose that \( \dim s < \dim \text{Princ}(s) - 1 \). Then there is a simplex \( t \in K \) such that \( s < t < \text{Princ}(s) \). That is, \( s \) is a proper face of \( t \) but \( t \neq \text{Princ}(s) \), a contradiction to the freeness of \( s \).

To define the notion of an elementary collapse of simplices, let \( K \) be a simplicial complex and \( s \in K \) a free simplex. Then

\[
K' := K - \{s, \text{Princ}_K(s)\}
\]
We say that a simplicial complex $K$ collapses (simplicially) to a subcomplex $L \subset K$, if $L$ can be obtained from $K$ by a finite sequence of elementary collapses. In this case we shall write $K \searrow L$. The complex $L$ is then also said to expand to $K$, written $L \nearrow K$.

If $K$ collapses to $L$, then the space $|L|$ is a deformation retract of the space $|K|$, and $|L|$ and $|K|$ have the same simple homotopy type. By its very definition, the relation $\searrow$ is transitive: if $K \searrow K'$ and $K' \searrow K''$, then $K \searrow K''$. Due to their combinatorial nature, collapses can be carried out algorithmically, see Section 7.

Definition 2.6. A finite sequence

$$K = K_0 \rightarrow K_1 \rightarrow \cdots \rightarrow K_m = L,$$

where each arrow represents a simplicial expansion or collapse, is called a formal deformation from $K$ to $L$.

Definition 2.7. A subcomplex $S \subset K$ of a simplicial complex $K$ is called a spine of $K$, if

1) $K$ collapses to $S$, and

2) $S$ does not possess a free simplex.

If $S$ is a spine of $K$, then we shall also refer to the polyhedron $|S|$ as a spine of the polyhedron $|K|$. Note that condition (2) is an absolute condition on $S$, independent of the ambient complex $K$. So if $L \subset K$ is a subcomplex with $K \searrow L$ and $S$ is a spine of $L$, then $S$ is also a spine of $K$. Furthermore, for such $K, L$, if $S$ is a spine of $K$ such that $L \searrow S$, then $S$ is a spine of $L$. These observations allow for induction arguments involving spines.

3. Filtered Spaces and Intersection Homology

A filtered topological space has intersection homology groups. Filtrations arise for example when a space has singular, i.e. non-manifold, points near which the space does not look like a Euclidean space. Stratification theory then tries to organize the singular points, according to their local type, into strata which themselves are manifolds (of various dimensions). The filtration is obtained by taking unions of such strata. Stratifications can generally be constructed for polyhedra of simplicial complexes, orbit spaces of group actions on manifolds, real or complex algebraic varieties, as well as for many interesting compactifications of non-compact spaces, e.g. various moduli spaces. A chief motivation for developing intersection homology was to find a theory which satisfies a form of Poincaré duality for singular spaces.
This duality principle holds for the ordinary homology of (closed, oriented) manifolds, but ceases to hold for ordinary homology in the presence of singularities. Intersection homology was introduced by Goresky and MacPherson in [13] and [14]; a comprehensive treatment can be found in [5]. Modern resources on intersection homology theory include [15], [12] and [11].

**Definition 3.1.** A *filtered space* is a Hausdorff topological space $X$ together with a filtration

$$X = X_n \supset X_{n-1} \supset \cdots \supset X_0 \supset X_{-1} = \emptyset$$

by closed subsets. We call $n$ the *formal dimension* of $X$. The connected components of the difference sets $X_j - X_{j-1}$ are called the *strata of formal dimension* $j$ of the filtered space. If $S$ is a stratum of formal dimension $j$, then $\text{codim} S := n - j$ is its *formal codimension* in $X$. Since all strata contained in $X_j - X_{j-1}$ have the same formal codimension $n - j$, we may call this number the formal codimension of $X_j - X_{j-1}$. We write $X_{\text{sing}}$ for the set of strata. The strata contained in $X_n - X_{n-1}$ are called the *regular strata*. The other strata are called *singular*. The union of the singular strata is called the *singular set* of $X$ and is denoted by $\Sigma_X$.

Note that a stratum is singular if and only if its formal codimension is positive. In practice there are various ways to assign formal codimensions to strata: Without further a priori knowledge or preprocessing, one may simply wish to take the geometric codimension in a given polyhedron. Better estimates may be obtained by first computing stratified spines and then taking geometric codimension in the spine, or by computing persistent local homology groups near singular points.

We recall the definition of the singular intersection homology groups $IH^p_i(X)$ of a filtered space $X$. The basic idea is the following: Suppose that $X$ is a filtered space for which global orientability can be defined, for example, a so-called pseudomanifold. If one defines a chain complex by allowing only chains that are transverse to the strata and computes its $i$-th homology, then, by a theorem of McCrory (see e.g. [13], Theorem 5.2), one obtains the cohomology $H^{n-i}(X)$ of $X$, where $n$ is the dimension of $X$ and $X$ is assumed to satisfy a certain normality condition. Hence, if one could move every chain to be transverse to the stratification, then Poincaré duality would hold if $X$ is orientable. However, as noted above, classical Poincaré duality fails for general oriented singular spaces, thus so does transversality. The idea of Goresky and MacPherson was to introduce a parameter, which they called a “perversity,” that specifies the allowable deviation from full transversality, and to associate a group to each value of the parameter, thereby obtaining a whole spectrum of groups ranging from cohomology to homology. The following definition of perversity is somewhat more general than the original definition in [13].

**Definition 3.2.** A *perversity* $\bar{p}$ is a function associating to each natural number $k = 0, 1, 2, \ldots$ an integer $\bar{p}(k)$ such that $\bar{p}(0) = 0$.

The natural number $k$ is to be thought of as the codimension of a stratum. Let $X$ be a filtered space and $\bar{p}$ a perversity. Recall that a *singular $i$-simplex* $\sigma$ in $X$ is a continuous map $\sigma : \Delta^i \to X$, where $\Delta^i$ denotes the standard $i$-simplex. The degree-$i$ singular chain group $C_i(X)$ of $X$ is freely generated by the singular $i$-simplices in $X$. Using the alternate sum of the codimension 1 faces of a singular simplex, one obtains a boundary map $\partial_i : C_i(X) \to C_{i-1}(X)$. Together with these boundary maps, the $C_i(X)$, $i = 0, 1, 2, \ldots$, form a chain complex $C_\ast(X)$, the singular chain complex of $X$. Its homology is ordinary homology $H_\ast(X)$. 
Definition 3.3. A singular $i$-simplex $\sigma : \Delta^i \to X$ is called $\bar{p}$-allowable if for every stratum $S \in \Sigma$, the preimage $\sigma^{-1}(S)$ is contained in the union of all $(i - \text{codim}(S) + \bar{p}(\text{codim}(S)))$-dimensional faces of $\Delta^i$. A chain $\xi \in C_i(X)$ is called $\bar{p}$-allowable, if every singular simplex $\sigma$ appearing with nonzero coefficient in $\xi$ is $\bar{p}$-allowable.

Definition 3.4. The group $IC^p_i(X)$ of $i$-dimensional (singular) intersection chains of perversity $\bar{p}$ is defined to be the subgroup of $C_i(X)$ given by all chains $\xi$ such that $\xi$ and $\partial \xi$ is $\bar{p}$-allowable.

The boundary map $\partial$ on $C_i(X)$ restricts to a map $\partial : IC^p_i(X) \to IC^p_{i-1}(X)$ due to the condition imposed on $\partial \xi$. Thus $\{(IC^p_i(X), \partial)\}$ forms a subcomplex $IC^p_*(X)$ of the singular chain complex $C_*(X)$.

Definition 3.5. The homology groups of the singular intersection chain complex,

$$IH^p_i(X) = H_i(\bar{IC}^p_*(X)),$$

are called the perversity $\bar{p}$ (singular) intersection homology groups of the filtered space $X$.

The groups thus defined have $\mathbb{Z}$-coefficients, $IH^p_i(X) = IH^p_i(X; \mathbb{Z})$. Groups $IH^p_i(X; G)$ with coefficients in any abelian group $G$ can also be defined in a straightforward manner. For the implementation of our algorithms, we chose to work with $G = \mathbb{Z}/2\mathbb{Z}$, as did Bendich and Harer [4].

Contrary to ordinary homology, intersection homology is not invariant under general homotopy equivalences. However, if one places suitable filtration conditions on a homotopy equivalence, the intersection homology groups do become invariant under such equivalences. Let us look at such conditions in more detail. We shall from now on, for simplicity of exposition and because this context already illustrates all important scientific issues, restrict our attention to filtered spaces of the form

$$X = X_n \supset X_{n-1} = \cdots = X_{n-k+1} = X_{n-k} = \Sigma_k \supset X_{n-k-1} = \cdots = X_1 = \emptyset,$$

which we will briefly denote as pairs $(X, \Sigma_k)$. (Thus $\Sigma_k$ has formal codimension $k$.) The methods introduced in the present paper can, without major difficulty, be extended to more general filtrations.

Definition 3.6. Let $(X, \Sigma_X)$ and $(Y, \Sigma_Y)$ be filtered spaces. A stratified map $f : (X, \Sigma_X) \to (Y, \Sigma_Y)$ is a continuous map $f : X \to Y$ such that $f(\Sigma_X) \subset \Sigma_Y$ and $f(X - \Sigma_X) \subset Y - \Sigma_Y$. Such a map is called codimension-preserving if $\text{codim}(\Sigma_X) = \text{codim}(\Sigma_Y)$.

Let $I = [0, 1]$ denote the compact unit interval. The cylinder on a filtered space $(X, \Sigma_X)$ is the filtered space $(X \times I, \Sigma_X \times I)$, i.e. $\Sigma_{X \times I} = \Sigma_X \times I$. We shall also write $(X, \Sigma_X) \times I$ for the pair $(X \times I, \Sigma_X \times I)$. If $n$ is the formal dimension of $X$, then the formal dimension of $X \times I$ is defined to be $n+1$ and we set $\text{codim}(\Sigma_X \times I) := \text{codim}(\Sigma_X) + 1$.

Definition 3.7. A stratified homotopy is a stratified map $H : (X \times I, \Sigma_X \times I) \to (Y, \Sigma_Y)$.

Thus a stratified homotopy maps $H(\Sigma_X \times I) \subset \Sigma_Y$ and $H((X - \Sigma_X) \times I) \subset Y - \Sigma_Y$; in particular, the tracks of the homotopy remain within the stratum where they start.

Definition 3.8. Stratified maps $f, g : (X, \Sigma_X) \to (Y, \Sigma_Y)$ are stratified homotopic if there exists a stratified homotopy $H : (X \times I, \Sigma_X \times I) \to (Y, \Sigma_Y)$ between $f$ and $g$, i.e. $H_0 = f$ and $H_1 = g$.

Note that if $f$ (or $g$) is in addition codimension-preserving, then a stratified homotopy $H$ between $f$ and $g$ is automatically codimension-preserving as well.
Definition 3.9. A stratified codimension-preserving map \( f : (X, \Sigma_X) \to (Y, \Sigma_Y) \) is called a **stratified homotopy equivalence**, if there exists a stratified (and then necessarily codimension-preserving) map \( g : (Y, \Sigma_Y) \to (X, \Sigma_X) \) such that \( g \circ f \) and \( f \circ g \) are stratified homotopic to the identity.

It is easy to show that singular intersection homology is invariant under stratified homotopy equivalences, see e.g. Friedman [12, Prop. 4.1.10, p. 135; Cor. 6.3.8, p. 271].

**Proposition 3.10.** A stratified homotopy equivalence \( f : (X, \Sigma_X) \to (Y, \Sigma_Y) \) of filtered spaces induces isomorphisms \( f_* : IH^p_i(X) \cong IH^p_i(Y) \) for all \( i \) and all \( p \).

Taking filtered spaces as objects and stratified homotopy equivalences as morphisms yields a category:

**Lemma 3.11.** The composition of stratified homotopy equivalences is a stratified homotopy equivalence.

**Proof.** Let \( f : (X, \Sigma_X) \to (Y, \Sigma_Y) \) and \( f' : (Y, \Sigma_Y) \to (Z, \Sigma_Z) \) be stratified homotopy equivalences with stratified homotopy inverses \( g : (Y, \Sigma_Y) \to (X, \Sigma_X) \) and \( g' : (Z, \Sigma_Z) \to (Y, \Sigma_Y) \). Since \( f \) and \( f' \) are codimension-preserving, the formal codimensions of the singular sets coincide,

\[
\text{codim}_X \Sigma_X = \text{codim}_Y \Sigma_Y = \text{codim}_Z \Sigma_Z.
\]

Let \( H : (X, \Sigma_X) \times I \to (X, \Sigma_X) \) be a stratified homotopy between \( H_0 = g \circ f \) and \( H_1 = \text{id}_X \), let \( H' : (Y, \Sigma_Y) \times I \to (Y, \Sigma_Y) \) be a stratified homotopy between \( H'_0 = g' \circ f' \) and \( H'_1 = \text{id}_Y \). As \( H, H' \) are stratified, the singular sets and their complements are mapped compatibly,

\[
H(\Sigma_X \times I) \subset \Sigma_X, \quad H((X - \Sigma_X) \times I) \subset X - \Sigma_X,
\]

\[
H'(\Sigma_Y \times I) \subset \Sigma_Y, \quad H'((Y - \Sigma_Y) \times I) \subset Y - \Sigma_Y.
\]

Recall that the concatenation \( F \concat F' \) of two homotopies \( F, F' : A \times I \to B \) such that \( F_1 = F'_0 \) is the homotopy \( F \concat F' : A \times I \to B \) given by

\[
(F \concat F')(a, t) = \begin{cases} F(a, 2t), & t \in [0, \frac{1}{2}] , \\ F'(a, 2t-1), & t \in [\frac{1}{2}, 1]. \end{cases}
\]

Note that if \( A' \subset A, B' \subset B \) are subspaces, then \( (F \concat F')(A' \times I) \subset B' \) if and only if \( F(A' \times I) \subset B' \) and \( F'(A' \times I) \subset B' \). Now let \( F : X \times I \to X \) be the homotopy given by the composition

\[
X \times I \xrightarrow{f \times \text{id}} Y \times I \xrightarrow{H'} Y \xrightarrow{g} X.
\]

Since

\[
F_1 = g \circ H_1' \circ (f \times 1) = g \circ f = H_0,
\]

we may concatenate to a homotopy \( G := F \concat H : X \times I \to X \). This is then a homotopy between \( G_1 = H_1 = \text{id}_X \) and

\[
G_0 = F_0 = g \circ H'_0 \circ (f \times 0) = gg'f'f.
\]

It satisfies \( G(\Sigma_X \times I) \subset \Sigma_X \), since

\[
F(\Sigma_X \times I) = g(H'((f \times \text{id})(\Sigma_X \times I))) \subset g(H'((\Sigma_X \times I))) \subset g(\Sigma_X) \subset \Sigma_X
\]

and \( H(\Sigma_X \times I) \subset \Sigma_X \). For the complements,

\[
F((X - \Sigma_X) \times I) = g(H'((f \times \text{id})(X - \Sigma_X \times I))) \subset g(H'((Y - \Sigma_Y \times I))) \subset g(Y - \Sigma_Y) \subset X - \Sigma_X
\]
and $H((X - \Sigma_X) \times I) \subset X - \Sigma_X$. Consequently, $G((X - \Sigma_X) \times I) \subset X - \Sigma_X$ and $G$ is a stratified homotopy between $(gg') \circ (f' f)$ and $id_X$. Note that $f' f$ and $gg'$ are codimension-preserving. By symmetry, a stratified homotopy $G' : (Z, \Sigma_Z) \times I \to (Z, \Sigma_Z)$ between $(f' f) \circ (gg')$ and $id_Z$ is obtained by the same method applied to stratified homotopies $K : (Y, \Sigma_Y) \times I \to (Y, \Sigma_Y)$ between $K_0 = f \circ g$ and $K_1 = id_Y$, and $K' : (Z, \Sigma_Z) \times I \to (Z, \Sigma_Z)$ between $K'_0 = f' \circ g'$ and $K'_1 = id_Z$. □

While singular intersection homology is not directly amenable to algorithmic computation, a simplicial version of intersection homology is. It must then be clarified under which conditions these versions are isomorphic. We will review this briefly and ask the reader to consult e.g. Friedman’s monograph [12] for details.

Suppose that the filtered space $X$ can be triangulated such that the filtration subspaces are triangulated by simplicial subcomplexes. Let $T : |K| \cong X$ be a choice of such a triangulation. The closed subspaces $X_j \subset X$ are given by $X_j = T(|K_j|)$ for subcomplexes $K_j \subset K$. One defines the simplicial intersection chain complex $IC^\bullet_{\partial T}(X)$ as a subcomplex of the simplicial chain complex of $K$, using $T$ and simplices of $K$ that are $\partial$-allowable with respect to the filtration $\{K_j\}$. The homology of $IC^\bullet_{\partial T}(X)$ is the simplicial intersection homology $IH^\bullet_{\partial T}(X)$ associated to the triangulation $T$. This is algorithmically computable, see Section 7 and [4].

The dependence on choices of triangulations can be controlled as follows: A piecewise-linear (PL) space is a second-countable Hausdorff space $X$ together with a collection $\mathcal{T}$ of locally finite triangulations, closed under simplicial subdivision, and such that any two triangulations in $\mathcal{T}$ have a common subdivision. Suppose that the PL space $X$ is PL filtered, that is, equipped with a filtration by closed subsets $X_j$ that are of the form $T(|K_j|)$ for some triangulation $T$ in $\mathcal{T}$. (One then calls $T$ compatible with the filtration.) Taking the direct limit of the simplicial groups $IH^\bullet_{\partial T}(X)$ over the directed set $\mathcal{T}$ defines the PL intersection homology $IH^\bullet_{\partial \mathrm{PL}}(X)$ of a PL filtered space $X$.

When does a particular simplicial intersection homology group compute PL intersection homology? A simplicial subcomplex $L \subset K$ is called full if membership of simplices in $L$ can be recognized on the vertex level, i.e.: whenever a simplex $s \in K$ has all of its vertices in $L$, then $s$ itself must be in $L$. A compatible triangulation $T \in \mathcal{T}$ of a PL filtered space $X$ is said to be full if $T$ triangulates the $X_j$ as full subcomplexes. Using finitely many subdivisions of a compatible triangulation, one sees that a PL filtered space always possesses a full triangulation. The condition of fullness can of course be checked algorithmically.

**Proposition 3.12.** (Goresky, MacPherson [10] Appendix; see also [12] Thm. 3.3.20, p. 119) If $T$ is a full (compatible) triangulation of a PL filtered space $X$, then the canonical map $IH^\bullet_{\partial T}(X) \to IH^\bullet_{\partial \mathrm{PL}}(X)$ is an isomorphism.

It remains to relate PL intersection homology to singular intersection homology. For a compact PL space $L$, let $e^o L$ denote the open cone $(\{0, 1\} \times L) / (0 \times L)$. A PL filtered space $X$ is called a PL CS set if it is locally cone-like and all filtration differences $X_j - X_{j-1}$ are $j$-dimensional PL manifolds. Points $x \in X_j - X_{j-1}$ must thus have open neighborhoods that are PL homeomorphic to $\mathbb{R}^j \times e^o L$ under a filtration preserving homeomorphism, where $L$ is some compact PL filtered space. Note that this concept creates in particular a logical connection between the topological manifold dimension of strata and the formal dimension of strata in the filtered space. Given a finite dimensional PL space $X$, there always exists a PL filtration of $X$ such that $X$ becomes a PL CS set with respect to this filtration. A given PL filtration may well not satisfy the PL CS condition.
Example 3.13. Let \( X = [K] \) be the polyhedron of the simplicial complex \( K \) generated by the \( 1 \)-simplices \( \{v_0, v_1\}, \{v_0, v_2\} \) and \( \{v_0, v_3\} \). Let \( \Sigma_X \subset X \) be the closed PL subspace given by the polyhedron of the complex generated by \( \{v_0, v_1\}, \{v_0, v_2\} \). Then \( \Sigma_X \) is PL homeomorphic to a compact interval and hence a 1-dimensional PL manifold (with boundary). The pair \((X, \Sigma_X)\) does not yet constitute a PL filtered space because no formal dimensions have been assigned. Can we make such an assignment in a way that will make the resulting PL filtered space into a PL CS set? If so, then we need to assign formal dimension 1 to \( X \), i.e. we are forced to set \( X_1 := \Sigma_X \). Since \( \Sigma_X \) is a proper subset of \( X \), the formal dimension of \( X \) would have to be at least 2 (and thus would not agree with the polyhedral dimension of \( X \)). If such a filtration made \((X, \Sigma_X)\) into a PL CS set, then the point \( v_0 \in \Sigma_X \) would have a neighborhood PL homeomorphic to a space of the form \( \mathbb{R}^1 \times c^0L \) for some compact PL space \( L \). No such \( L \) exists. (For dimensional reasons, \( L \) would have to be empty, but the neighborhood of \( v_0 \) is not homeomorphic to \( \mathbb{R}^1 \).) We conclude that the PL filtered space \((X, \Sigma_X)\) is not a PL CS set. If instead one took \( \Sigma_X = X_0 = \{v_0, \ldots, v_3\} \) and \( X_1 = X \), then \((X, \Sigma_X)\) would be a PL CS set.

Proposition 3.14. (Friedman [12, Thm. 5.4.2, p. 229]) If \( X \) is a PL CS set, then there is an isomorphism \( IH_i^{\text{PL}}(X) \cong IH_i^*(X) \) between PL and singular intersection homology groups.

Together, Propositions 3.12 and 3.14 provide sufficient conditions for simplicial intersection homology to compute singular intersection homology. The upshot is that every PL space \( X \) has a PL filtration \( \{X_j\} \) which makes \( X \) into a PL CS set, and a triangulation whose simplicial intersection homology computes the singular intersection homology of \((X, \{X_j\})\).

A particularly important class of singular spaces are pseudomanifolds. An \( n \)-dimensional PL pseudomanifold is a polyhedron \( X \) for which some (and hence every) triangulation has the following property: Every simplex is the face of some \( n \)-simplex, and every \((n-1)\)-simplex is a face of exactly two \( n \)-simplices. Pseudomanifolds admit a concept of orientability, and if a given pseudomanifold is oriented, its intersection homology will satisfy a generalized form of Poincaré duality.

The following small example shows that direct computation of intersection homology from the Vietoris-Rips complex of a point cloud does not usually yield the correct intersection homology of an underlying space near which the points are sampled, even when the points have been sampled “well” in the sense that the location of the singular set is known and the Vietoris-Rips complex is homotopy equivalent to the underlying space (and hence its ordinary homology is correct).

Example 3.15. Let \( 0 \) denote the zero-perversity whose value is 0 on every codimension, and let \( -1 \) the perversity whose value is \(-1\) on every positive codimension. We shall write \( \mathbb{Z}_2 \) for \( \mathbb{Z}/2\mathbb{Z} \). The figure eight space \( S^1 \vee S^1 \), a wedge of two circles, equipped with the obvious filtration with one singular point in codimension 1, has intersection homology

\[
IH_{1}^{0}(S^1 \vee S^1; \mathbb{Z}_2) = \begin{cases} 
\mathbb{Z}_2, & \text{if } i = 1 \\
\mathbb{Z}_2, & \text{if } i = 0 \\
0, & \text{else;}
\end{cases}
\]

\[
IH_{i}^{-1}(S^1 \vee S^1; \mathbb{Z}_2) = \begin{cases} 
\mathbb{Z}_2, & \text{if } i = 0 \\
0, & \text{else.}
\end{cases}
\]

Figure [1] shows 12 points near an embedding of \( S^1 \vee S^1 \) in the plane \( \mathbb{R}^2 \), as well as an associated Vietoris-Rips complex with polyhedron \( X \). The singular point \( s \) of \( S^1 \vee S^1 \) is one of the
12 points and is located in the middle of the figure. The polyhedron $X$ is 2-dimensional and filtered by $\{s\} = X_0 \subset X_2 = X$. Its intersection homology groups are

$$IH_i^0(X;\mathbb{Z}_2) = IH_i^{-1}(X;\mathbb{Z}_2) = \begin{cases} \mathbb{Z}_2^2, & \text{if } i = 0 \\ 0, & \text{else,} \end{cases}$$

which are not isomorphic to the above groups of $S^1 \vee S^1$. A spine $X'$ of $X$ is shown in Figure 2. It is 1-dimensional and filtered by $\{s\} = X'_0 \subset X'_1 = X'$. A computer calculation of its intersection homology yields

$$IH_i^0(X';\mathbb{Z}_2) = \begin{cases} \mathbb{Z}_2^2, & \text{if } i = 1 \\ \mathbb{Z}_2, & \text{if } i = 0 \\ 0, & \text{else;} \end{cases}$$

$$IH_i^{-1}(X';\mathbb{Z}_2) = \begin{cases} \mathbb{Z}_2^2, & \text{if } i = 0 \\ 0, & \text{else;} \end{cases}$$

which do agree with the intersection homology of $S^1 \vee S^1$. Of course, one may readily deduce this from the fact that in this particular example it so happens that the spine is even stratum preserving homeomorphic to $S^1 \vee S^1$, which obviously does not always happen. (We will return to this example in Section 8).

Such examples suggest the idea of using simplicial collapse processes and spines to explore the intersection homology of Vietoris-Rips and other simplicial complexes. However, contrary to ordinary homology, intersection homology is not generally invariant under arbitrary simplicial collapses, so a second new idea is needed, to be developed in the next section: the idea of stratified simplicial collapses and expansions.
We define stratified (simplicial) collapses and expansions, stratified formal deformations and stratified spines. We begin by observing that if in a simplicial complex one looks for pseudomanifolds obtainable by collapses (i.e. the complex is a thickening of an unknown pseudomanifold), then one must seek these pseudomanifolds among the spines of that complex.

Lemma 4.1. Let \( K \) be a simplicial complex and \( L \subset K \) a subcomplex. If \( K /\n L \) and \( |L| \) is a pseudomanifold, then \( L \) is a spine of \( K \).

Proof. Let \( n \) be the dimension of \( |L| \). Suppose that \( L \) is not a spine of \( K \). Then \( L \) possesses a free simplex \( s \). Let \( p = \text{Princ}_L(s) \) be the associated principal simplex. We have \( \dim p \leq n \). If \( \dim p = n \), then \( \dim s = n - 1 \) by Lemma 2.3. So \( s \) is an \((n-1)\)-simplex which is the face of precisely one \( n \)-simplex, contradicting the fact that in an \( n \)-dimensional pseudomanifold, every \((n-1)\)-simplex is the face of precisely two \( n \)-simplices. Suppose that \( \dim p < n \). Then \( p \), not being the face of any simplex in \( L \), is in particular not the face of any \( n \)-simplex, contradicting the fact that in an \( n \)-dimensional pseudomanifold, every simplex must be the face of some \( n \)-simplex. \qed

Definition 4.2. A layered simplicial complex is a triple \((K, C, S)\), where \( K \) is a simplicial complex and \( C, S \) are disjoint subcomplexes of \( K \). Simplices of \( K \) which are neither in \( C \) nor in \( S \) are called intermediate simplices. We shall write \( \text{IM}(K, C, S) \) for the set of intermediate simplices.

Note that in general \( \text{IM}(K, C, S) \) is merely a subset, not a subcomplex, of \( K \).

Definition 4.3. A divided simplicial complex is a pair \((K, S^0)\), where \( K \) is a simplicial complex and \( S^0 \subset K^0 \) is a set of vertices of \( K \).
A divided simplicial complex \((K, S^0)\) gives rise to a layered simplicial complex \((K, C, S)\) such that the set of vertices of \(S\) is \(S^0\), as follows: Take \(S\) to consist of all simplices of \(K\) whose vertices lie in \(S^0\). (Note that this is indeed a subcomplex of \(K\).) Take \(C\) to consist of all simplices of \(K\) whose vertices lie in the complement \(C^0 := K^0 - S^0\). (Again, this is a subcomplex of \(K\).) We call \((K, C, S)\) the associated layered complex of the divided complex \((K, S^0)\). In the associated layered complex, the intermediate simplices are those simplices of \(K\) that have at least one vertex in \(S^0\) and one vertex in \(K^0 - S^0\). Hence the dimension of an intermediate simplex in an associated layered complex is at least 1.

Let \((K, C, S)\) be a layered simplicial complex. Suppose that
\[
K = K_0 \setminus \ldots \setminus K_1 \setminus K_2 \setminus \ldots \setminus K_m = K_S
\]
is a finite sequence of elementary collapses, such that \(K_{i+1} = K_i - \{s, p\}\), where \(p\) is a simplex in \(S\) which is principal in \(K_i\), and \(s\) is a face of \(p\) which is free in \(K_i\). Note that since \(S\) is a subcomplex, \(s\) is in \(S\). Since \(C\) and \(S\) are disjoint, neither \(p\) nor \(s\) can be a simplex of \(C\). Hence \(C\) remains a subcomplex of \(K_i\) for every \(i\), and in particular is a subcomplex of \(K_S\). Set
\[
S_i = K_i \cap S.
\]
The intersection \(A \cap B\) of two subcomplexes \(A, B \subset L\) of a simplicial complex \(L\) is a subcomplex of \(A\), of \(B\), and of \(L\). Hence \(S_i \cap S_{i+1}\) is a subcomplex of \(S_i\) for every \(i\). The simplices \(p\) and \(s\) lie in the complex \(S_i\). As \(p\) is principal in \(K_i\), it is in particular principal in the subcomplex \(S_i\). Furthermore, as \(s\) is free in \(K_i\), it is also free in the subcomplex \(S_i\). This shows that \(S_{i+1}\) is obtained from \(S_i\) by an elementary collapse \(S_i \setminus S_{i+1}\). Hence there is a finite sequence of elementary collapses
\[
S = S_0 \setminus S_1 \setminus S_2 \setminus \ldots \setminus S_m =: S'.
\]
Since \(S'\) is obtained by removing simplices of \(S\), the subcomplexes \(C\) and \(S'\) of \(K_S\) are of course still disjoint and hence \((K_S, C, S')\) is a layered complex.

**Definition 4.4.** An \(S\)-collapse of the layered simplicial complex \((K, C, S)\) is any layered simplicial complex \((K_S, C, S')\) obtained by the collapse process described above. If \(m = 1\), we shall refer to \(K_0 \setminus K_1\) also as an elementary \(S\)-collapse.

Loosely, an \(S\)-collapse is thus obtained by collapsing only simplices of the subcomplex \(S\). Since the definition of a layered complex is symmetric in \(C\) and \(S\), the notion of a \(C\)-collapse can be defined by interchanging the role of \(C\) and \(S\) in the above collapse process. Thus:

**Definition 4.5.** A \(C\)-collapse of the layered simplicial complex \((K, C, S)\) is any layered simplicial complex \((K_C, C', S)\) obtained by the collapse process described above, where only simplices of \(C\) are eligible for elementary collapses. If \(m = 1\), we shall speak of an elementary \(C\)-collapse.

Now, as \(C\) has been left intact in any \(S\)-collapse \((K_S, C, S')\),
\[
K = K_0 \setminus K_1 \setminus K_2 \setminus \ldots \setminus K_m = K_S,
\]
we may execute a \(C\)-collapse
\[
K_S = (K_S)_0 \setminus (K_S)_1 \setminus (K_S)_2 \setminus \ldots \setminus (K_S)_m = (K_S)_C,
\]
\[
(K_S)_{i+1} = (K_S)_i - \{s_i', p_i'\},
\]
on \((K_S, C, S')\), yielding a layered simplicial complex \(((K_S)_C, C', S')\). Is \(p_0'\) principal in \(K\)? The simplex \(p_0'\) lies in \(C\) and is principal in
\[
K_S = K - \{s_0, p_0, \ldots, s_{m-1}, p_{m-1}\}.
\]
So \( p_0^l \) is not the proper face of any simplex in \( K_3 \). Hence, if \( p_0^l \) were not principal in \( K \), then \( p_0^l \) would have to be the face of some \( p_i \). But this would place \( p_0^l \) in the complex \( S \) which is impossible as \( S \) and \( C \) are disjoint. We conclude that \( p_0^l \) is principal even in \( K \). For the same reason, \( s_0^l \) is free even in \( K \): We know \( s_0^l \) lies in \( C \) and is free in \( K_3 \). So \( s_0^l \) is not the proper face of any simplex in \( K_3 \) other than \( p_0^l \). If \( s_0^l \) were not free in \( K \), then \( s_0^l \) would be the proper face of some simplex \( t \) in \( K \), \( t \neq p_0^l \). Then \( s_0^l \) would be the proper face of some \( p_i \), which is again impossible. Thus the elementary collapse

\[ K = K_0^l \setminus K_1^l := K_0^l \setminus \{ s_0^l, p_0^l \} \]

is defined. Similarly, one then sees by an easy induction argument that \( p_i^l \) is principal in \( K_i^l \) and \( s_i^l \) is free in \( K_i^l \), whence we may define

\[ K_{i+1}^l = K_i^l \setminus \{ s_i^l, p_i^l \}. \]

We thus obtain a \( C \)-collapse \((K_C, C'', S')\),

\[ K = K_0^l \setminus K_1^l \setminus K_2^l \setminus \cdots \setminus K_r^l = K_C. \]

It is immediately clear that \( p_0 \) is principal in \( K_C \), since it is so even in \( K \). For the same reason, \( s_0 \) is free in \( K_C \). Thus the elementary collapse

\[ K_C = (K_C)_0 \setminus (K_C)_1 := (K_C)_0 \setminus \{ s_0, p_0 \} \]

is defined. Similarly, one then sees by an easy induction argument that \( p_i \) is principal in \((K_C)_i\), and \( s_i \) is free in \((K_C)_i\), whence we may define

\[ (K_C)_{i+1} = (K_C)_i \setminus \{ s_i, p_i \}. \]

We thus obtain an \( S \)-collapse \((K_C)_S, C'', S'\),

\[ K_C = (K_C)_0 \setminus (K_C)_1 \setminus (K_C)_2 \setminus \cdots \setminus (K_C)_m = (K_C)_S. \]

Now note that

\[ (K_C)_S = (K_S)_C, \quad C'' = C', \quad S'' = S'. \]

Thus \( S \)-collapses and \( C \)-collapses are commuting operations on layered simplicial complexes.

Notably with a view towards algorithm design, it is important to know that \( S \)- and \( C \)-collapses do not affect the set of intermediate simplices:

**Lemma 4.6.** Let \((K, C, S)\) be the associated layered complex of a divided complex. If \((K', C', S')\) has been obtained from \((K, C, S)\) by an \( S \)-collapse, then

\[ \text{IM}(K', C, S') = \text{IM}(K, C, S). \]

If \((K', C', S')\) has been obtained from \((K, C, S)\) by a \( C \)-collapse, then

\[ \text{IM}(K', C', S') = \text{IM}(K, C, S). \]

**Proof.** By symmetry, it suffices to consider \( S \)-collapses. Then \( K' = K \setminus \{ s, p \} \), \( S' = S \setminus \{ s, p \} \), with \( p \in S \), \( p \) principal in \( K \), \( s \) a proper face of \( p \) and \( s \) free in \( K \). The inclusion

\[ \text{IM}(K', C, S') \subset \text{IM}(K, C, S) \]

follows from \( K' \subset K \) and \( S' \subset S \). Conversely, suppose that \( t \in \text{IM}(K, C, S) \). Then \( t \neq s \) and \( t \neq p \), since \( t \notin S \), while \( s, p \in S \). Therefore, \( t \in K \setminus \{ s, p \} = K' \). Since \( t \) is intermediate in \((K, C, S)\) and \((K, C, S)\) comes from a divided complex, \( t \) has a vertex \( v \in C \) and a vertex \( w \in S \). In particular, \( t \) has positive dimension. We claim that \( w \in S' \): As \( p \) has positive dimension, \( w \neq p \). If \( w \) were equal to \( s \), then \( s \) would be a proper face of both \( t \) and \( p \), with \( t \neq p \). This would contradict the freeness of \( s \) in \( K \). We deduce that \( w \neq s \), so that \( w \in S \setminus \{ s, p \} \). This proves the claim. Thus \( t \) is a simplex of \( K' \) which possesses a vertex \( v \in C \) and a vertex \( w \in S' \), showing that \( t \) is intermediate in \((K', C, S')\). \( \square \)
The most interesting aspect of stratified collapses is the treatment of intermediate simplices. Let \((K,S)\) be a layered simplicial complex and suppose that

\[ K = K_0 \setminus K_1 = K_0 - \{s, p\} \]

is an elementary collapse, where

1. \(p\) is an intermediate simplex of \((K,C,S)\),
2. \(p\) is principal in \(K_0\),
3. \(s\) is a face of \(p\) which is free in \(K_0\), and
4. \(t\) is a simplex of \(S\) which is a proper face of \(p\), then \(t\) is a proper face of \(s\).

Put \(C_1 := K_1 \cap C \) and \(S_1 := K_1 \cap S\). Then \(C_1\) and \(S_1\) are subcomplexes of \(K_1\) and they are disjoint. Consequently, \((K_1,C_1,S_1)\) is a layered simplicial complex.

**Lemma 4.7.** For any layered simplicial complex and simplices \(s, p\) as above, we have \(S_1 = S\).

**Proof.** Since \(p\) is intermediate in \((K,C,S)\), \(p \notin S\). Hence \(S_1 = S - \{s, p\} = S - \{s\}\). We claim that \(s \notin S\). Suppose \(s\) were a simplex in \(S\). Then, as \(s\) is a proper face of \(p\) (by freeness), we could take \(t = s\) in condition (iv) above and conclude that \(t = s\) is a proper face of itself, a contradiction. Hence \(s \notin S\) as claimed. \(\Box\)

**Lemma 4.8.** If \((K,C,S)\) is the associated layered complex of a divided simplicial complex \((K,S^0)\), then \(C_1 = C\).

**Proof.** Since \(p\) is intermediate in \((K,C,S)\), \(p \notin C\). Hence \(C_1 = C - \{s, p\} = C - \{s\}\). (This is true even if \((K,C,S)\) does not come from a divided complex.) We claim that if \((K,C,S)\) is associated to \((K,S^0)\), then \(s \notin C\). Indeed, as \(p \notin C\), \(p\) must then have at least one vertex \(v \in S^0\). Then \(t = \{v\}\) is a simplex of \(S\) and \(t\) is a proper face of \(p\). (Note that \(\dim p \geq 1\), as \(p\) is intermediate in an associated complex.) By condition (iv) above, \(\{v\}\) is a face of \(s\). But \(v \notin C^0 = K^0 - S^0\), so \(s\) has a vertex which is not in \(C^0\). It follows that \(s\) cannot be in \(C\), as claimed. \(\Box\)

Let us assume that \((K,C,S)\) is the associated layered complex of a divided simplicial complex \((K,S^0)\). Then, by Lemmas 4.7 and 4.8, \((K_1,C_1,S_1) = (K_1,C,S)\). It follows that

\[
\text{IM}(K_1,C_1,S_1) = \text{IM}(K_1,C,S) = \{s \in K_1 \mid s \notin C \text{ and } s \notin S\}
\]

\[
= \{s \in K \mid s \notin C \text{ and } s \notin S\} \cap K_1 = \text{IM}(K,C,S) \cap K_1.
\]

Thus the notion of intermediacy is preserved under the passage from \(K\) to \(K_1\): a simplex in \(K_1\) is intermediate in \((K_1,C_1,S_1)\) if and only if it is intermediate in \((K,C,S)\). Note that neither \(s\) nor \(p\) can be a vertex. For if \(s\) were a vertex, then \(s = \{v\}\) with \(v \in S^0\) or \(v \in K^0 - S^0 = C^0\). In the case \(v \in S^0\), we have \(s \in S\) and since \(s\) is a proper face of \(p\), (iv) implies that \(s\) is a proper face of itself, which is impossible. On the other hand, if \(v \in C^0\), then \(p = \{u,v\}\) with \(u \in S^0\) (since \(p\) is intermediate, and a free face has codimension 1 in its principal simplex). Then \(t := \{u\}\) is a simplex of \(S\) which is a proper face of \(p\) but not a proper face of \(s = \{v\}\), contradicting (iv). Thus \(s\) is not a vertex. (Since \(s\) is a proper face of \(p\), the latter can of course not be a vertex either.) Thus \(K_1\) and \(K\) have the same vertex set, \((K_1)^0 = K^0\). In particular, the partition of \(K^0\) into \(S^0\) and its complement \(C^0\) can be regarded as a partition of \((K_1)^0\). Thus we have a well-defined divided complex \((K_1,S^0)\).

**Lemma 4.9.** The layered complex \((K_1,C,S)\) is associated to the divided complex \((K_1,S^0)\).

**Proof.** If \(s\) is a simplex of \(K_1\) whose vertices are in \(S^0\), then \(s\) is in particular a simplex of \(K\) whose vertices are in \(S^0\), and thus \(s \in S\), as \((K,C,S)\) is associated to \((K,S^0)\). Conversely, suppose that \(s \in K_1\) is a simplex in \(S\). Then \(s\) is in particular a simplex of \(K\) which is in \(S\),
and thus all vertices of \( s \) are in \( S^0 \), as \((K,C,S)\) is associated to \((K,S^0)\). Analogous reasoning applied to \( C \) instead of \( S \) will show that \( C \) consists precisely of those simplices in \( K_1 \) whose vertices are in \( K^0 - S^0 \).

**Definition 4.10.** We say that the layered simplicial complex \((K_1,C,S)\) described above has been obtained from the associated layered simplicial complex \((K,C,S)\) of a divided complex \((K,S^0)\) by an elementary intermediate collapse.

Lemma 4.9 allows for an iterative execution of elementary intermediate collapses. Thus we may define:

**Definition 4.11.** The layered simplicial complex \((K_t,C,S)\) has been obtained from the associated layered simplicial complex \((K,C,S)\) of a divided complex \((K,S^0)\) by an intermediate collapse, if \((K_t,C,S)\) is produced by a finite sequence of elementary intermediate collapses starting from \((K,C,S)\).

**Remark 4.12.** In the context of condition (iv), let \( t \) be a simplex of \( S \) which is a proper face of \( p \in \text{IM}(K,C,S) \). Then, by (iv), \( t \) is a proper face of \( s \), which is itself a proper face of \( p \). Therefore,

\[ \dim t \leq \dim p - 2. \]

This can be regarded as an echo of the pseudomanifold condition: In a triangulation of an \( n \)-dimensional pseudomanifold, a simplex is principal if and only if it has dimension \( n \). (For if a principal simplex had smaller dimension, then it would have to be the face of some \( n \)-simplex and so could not be principal.) Then if \( t \) is any simplex in the singular set \( \Sigma \),

\[ \dim t \leq \dim \Sigma \leq n - 2 = \dim p - 2. \]

(We note however, that \( p \) in the present situation does not actually have a free face \( s \).)

**Definition 4.13.** Let \((K,C,S),(K',C',S')\) be layered complexes associated to divided simplicial complexes. We say that \((K',C',S')\) has been obtained from \((K,C,S)\) by an elementary layered collapse, if there is an elementary \( C' \)-, \( S' \)-, or intermediary collapse of a simplex in \((K,C,S)\) that yields \((K',C',S')\). In that case, we say that \((K,C,S)\) is obtained from \((K',C',S')\) by an elementary layered expansion. Let \((X,\Sigma) = ([K],[S])\) and \((X',\Sigma') = ([K'],[S'])\) be the polyhedral pairs determined by the layered complexes. In the above situation, we then say that \((X',\Sigma')\) has been obtained from \((X,\Sigma)\) by an elementary stratified collapse and \((X,\Sigma)\) from \((X',\Sigma')\) by an elementary stratified expansion. A layered collapse from \((K,C,S)\) to \((K',C',S')\) is a finite sequence of elementary layered collapses; similarly for layered expansions. For the polyhedral pairs, this leads to the notion of stratified collapses and stratified expansions. A layered formal deformation from \((K,C,S)\) to \((K',C',S')\) is a finite sequence of transformations, each of which is either a layered collapse or a layered expansion, starting from \((K,C,S)\) and ending with \((K',C',S')\). The associated sequence of polyhedral pairs is called a stratified formal deformation from \((X,\Sigma)\) to \((X',\Sigma')\).

Classical elementary collapses can be executed in any order, since a free face cannot ever become non-free by performing classical collapses. Our stratified theory involves three different types of collapses and we must carefully investigate the effects of sequentially ordering these types, particularly as this is relevant for the algorithmic implementation (Section 7).

**Lemma 4.14.** If \( p \) is a simplex and \( q < p \) a face of codimension at least 2, then for any proper face \( s < p \) with \( q < s \), there exists a second proper face \( t < p \), \( t \neq s \), such that \( q < t \).

**Proof.** The face \( s \) is obtained from \( p \) by omitting at least one vertex \( u \). The face \( q \) is obtained from \( s \) by omitting at least one vertex \( v \), \( v \neq u \). Then \( t = q \cup \{u\} \) does the job. \( \square \)
Proposition 4.15. Let \((K,C,S)\) be the associated layered complex of a divided simplicial complex. If \((K,C,S)\) admits no \(S\)-collapse and \((K',C,S)\) is obtained from \((K,C,S)\) by an intermediate collapse, then \((K',C,S)\) still does not admit an \(S\)-collapse.

Proof. The complex \(K'\) is of the form

\[ K' = K - \{ f, p \}, \]

where \(f\) and \(p\) satisfy the conditions (i)–(iv) of an intermediate collapse. In particular, \(p \in \text{IM}(K',C,S)\), \(p\) is principal in \(K\), and \(f < p\) is free in \(K\). We argue by contradiction: Suppose that \((K',C,S)\) does admit an \(S\)-collapse. Then there is a simplex \(q \in S\) which is principal in \(K'\) and has a proper face \(s < q\) which is free in \(K'\). Since there is no \(S\)-collapse possible in \((K,C,S)\), either \(q\) is not principal in \(K\), or \(q\) has no free face in \(K\).

Suppose first that \(q\) is not principal in \(K\). Then \(q < p\) or \(q < f\). If \(q < p\), then by condition (iv) for intermediate collapses, \(q < f\) (as \(q \in S\)). So we may assume \(q < f\). Thus \(q\) is a face of codimension at least 2 of \(p\). By Lemma 4.14, there exists a proper face \(r < p\) such that \(r \neq f\) and \(q < r\). Note that \(r\) is a simplex of \(K'\). Thus \(q\) is not principal in \(K'\), a contradiction. We conclude that \(q\) must already be principal in \(K\) and \(q\) has no free face in \(K\). In particular, \(s\) is not free in \(K\), but \(s\) is free in \(K'\). Therefore, \(s < q\) or \(s < f\). If \(s < p\), then by condition (iv) for intermediate collapses, \(s < f\) (as \(s \in S\)). So we may assume \(s < f\). Thus \(s\) is a face of codimension at least 2 of \(p\). By Lemma 4.14, there exists a proper face \(r < p\) such that \(r \neq f\) and \(s < r\). Note that \(r\) is a simplex of \(K'\). If \(r = q\), then \(q < p\), so \(q\) is not principal in \(K\), a contradiction. Hence \(r \neq q\). But then \(s < r \in K'\) and \(s < q \in K'\) and \(r \neq q\), which contradicts the freeness of \(s\) in \(K'\). Thus \(q\) and \(s\) as above cannot exist and \((K',C,S)\) does not admit an \(S\)-collapse, as was to be shown. 

The following example illustrates the process of layered collapses and shows in particular that intermediate collapses, carried out after all possible \(S\)- and \(C\)-collapses have been performed, may enable new \(C\)-collapses (though by the proposition, they cannot enable new \(S\)-collapses).

Example 4.16. Let \(p = \{s_0, s_1, c_0, c_1\}\) be a 3-simplex with vertices \(s_0, s_1, c_0, c_1\) and let \(K\) be the simplicial complex generated by \(p\). Let \(S^0 = \{s_0, s_1\}\), determining a divided complex \((K,S^0)\). The complex \(S\) of the associated layered complex \((K,C,S)\) is the simplicial subcomplex generated by the 1-simplex \(\{s_0, s_1\}\) and \(C\) is the subcomplex generated by the 1-simplex \(\{c_0, c_1\}\), see Figure 4.

No \(S\)-collapse is possible in \((K,C,S)\), since the 1-simplex \(\{s_0, s_1\}\), while principal in \(S\), is not principal in \(K\). Similarly, no \(C\)-collapse is possible. However, there is one possible intermediate collapse: The simplex \(p = \{s_0, s_1, c_0, c_1\}\) is intermediate in \((K,C,S)\), principal in \(K\), and \(s = \{s_0, s_1, c_1\}\) is a free face of \(p\). We have to verify condition (iv): The simplices \(t\) in \(S\) are \(\{s_0, s_1\}\), \(\{s_0\}\) and \(\{s_1\}\). All of these are proper faces of \(p\), so the conclusion of (iv) must be checked. Indeed, all these \(t\) are proper faces of \(s = \{s_0, s_1, c_1\}\). Thus there is an admissible intermediate collapse \(K \backslash K_1 = K - \{s, p\}\). The complex \(K_1\) is 2-dimensional, with three 2-simplices. No \(C\)-collapse or \(S\)-collapse is feasible in \((K_1,C,S)\).

The simplex \(p = \{s_1, c_0, c_1\}\) is intermediate in \((K_1,C,S)\), principal in \(K_1\), and \(s = \{s_1, c_1\}\) is a free face of \(p\). We verify condition (iv): The simplices \(t = \{s_0, s_1\}\) and \(t = \{s_0\}\) in \(S\) are not faces of \(p\). But \(t = \{s_1\}\) is a proper face of \(p\), so the conclusion of (iv) must be checked for this \(t\). Indeed, \(t = \{s_1\}\) is a proper face of \(s = \{s_1, c_1\}\). Thus there is an admissible intermediate collapse \(K_1 \backslash K_2 = K_1 - \{s, p\}\). The complex \(K_2\) has precisely two 2-simplices.

The simplex \(p = \{s_0, c_0, c_1\}\) is intermediate in \((K_2,C,S)\), principal in \(K_2\), and \(s = \{s_0, c_1\}\) is a free face of \(p\). We verify condition (iv): The simplices \(t = \{s_0, s_1\}\) and \(t = \{s_1\}\) in \(S\) are
not faces of \( p \). But \( t = \{s_0\} \) is a proper face of \( p \), so the conclusion of (iv) must be checked for this \( t \). Indeed, \( t = \{s_0\} \) is a proper face of \( s = \{s_0, c_1\} \). Thus there is an admissible intermediate collapse \( K_2 \setminus K_1 = K_2 - \{s, p\} \). The complex \( K_3 \) has precisely one 2-simplex.

Note that \((K_3, C, S)\) does not admit an intermediate collapse, but it does admit a \( C \)-collapse: The 1-simplex \( \{c_0, c_1\} \) is in \( C \), is principal in \( K_3 \) and has the free face \( \{c_1\} \). The corresponding elementary \( C \)-collapse yields a layered complex \((K_{3C}, C', S)\) with \( C' = \{\{c_0\}\} \). Although the complex \( K_{3C} \) (forgetting the layer structure) is collapsible to a point, the layered complex \((K_{3C}, C', S)\) admits no \( C \)-collapse, no \( S \)-collapse, and no intermediate collapse.

**Proposition 4.17.** Let \((K, C, S)\) be the associated layered complex of a divided simplicial complex \((K, S^0)\). Suppose that \((K, C, S)\) does not admit an intermediate collapse. If \((K', C', S)\) is obtained from \((K, C, S)\) by a \( C \)-collapse, then \((K', C', S)\) still does not admit an intermediate collapse.

**Proof.** The complex \( K' \) has the form \( K' = K - \{f, p\} \), \( p \in C \), \( p \) principal in \( K \), and \( f < p \) free in \( K \). Since \( f \) and \( p \) are in \( C \), we have \( C' = C - \{f, p\} \). We argue by contradiction: Suppose an intermediate collapse in \((K', C', S)\) were possible. Then there would exist simplices \( g, q \) in \( K' \) such that

(a) \( q \in \text{IM}(K', C', S) \),
(b) \( q \) is principal in \( K' \),
(c) \( g < q \) with \( g \) free in \( K' \),
(d) for every \( t \in S \): if \( t < q \), then \( t < g \).

Statement (a) implies that \( q \not\in S \) and \( q \not\in C' = C - \{f, p\} \). As \( q \) lies in \( K' \) it must be different from \( f \) and \( p \). Thus \( q \not\in C \). Hence is already intermediate in \((K, C, S, q \in \text{IM}(K, C, S))\).
Suppose $q$ were not principal in $K$. Then, as it is principal in $K'$ by (b), $q < p$ or $q < f$. If $q < f$, then in particular $q < p$, so we may assume $q < p$. But this places $q$ into $C$, a contradiction to $q \in \text{IM}(K,C,S)$. Therefore, $q$ is already principal in $K$.

Is $g$ free in $K$? If not, then (since it is free in $K'$) $g < p$ or $g < f$. If $g < f$, then $g < p$, so we may assume the latter, which implies that $g \in C$. So $g$ has the form $g = \{c_0, \ldots, c_k\}$ for vertices $c_0, \ldots, c_k \in C^0 = K_0 - S^0$. Since $g$ is a codimension one face of $q$ (Lemma 2.3), $q$ must have the form $q = \{c_0, \ldots, c_k, s\}$. Since $q$ is intermediate, the vertex $s$ must be in $S^0$. Take $t := \{s\}$. Then $t \in S$ and $t < q$. By (d), $t < g$ and we reach a contradiction. We conclude that $g$ is free in $K$.

We have seen that $q \in \text{IM}(K,C,S)$, $q$ is principal in $K$, and $g$ is a free face of $q$ in $K$. But $(K,C,S)$ does not admit an intermediate collapse. Consequently, condition (iv) for intermediate collapses must be violated for $g, q$ in $(K,C,S)$. Thus there must exist a $t \in S$ such that $t < q$ but $t$ is not a proper face of $g$ in $K$. Such a $t$ must be in $K'$, and we arrive at a contradiction to (d). Therefore, an intermediate collapse in $(K',C',S)$ is not possible. \qed

**Definition 4.18.** Let $(K,C,S)$ be the associated layered simplicial complex of a divided complex. A layered simplicial complex $(K',C',S')$ is called a layered spine of $(K,C,S)$ if $(K',C',S')$ can be obtained from $(K,C,S)$ by a layered collapse and $(K',C',S')$ does not admit any further layered collapse (though it may admit further ordinary collapses). In this case, we say that the polyhedral pair $(X',\Sigma') = (|K'|,|S'|)$ is a stratified spine of $(X,\Sigma) = (|K|,|S|)$.

As Example 4.16 shows, a layered spine of a layered complex $(K,C,S)$ need not be a spine (in the ordinary sense) of the underlying complex $K$. However, if the polyhedron of the underlying simplicial complex of a layered spine is a pseudomanifold, then it will be a spine, by Lemma 4.1. Note that the polyhedron of $K_C$ in Example 4.16 is not a pseudomanifold. Section 8 contains several example calculations of stratified spines, and their intersection homology, in simplicial complexes coming from point data.

5. **FREELY ORTHOGONAL DEFORMATION RETRACTIONS**

The polyhedron of an elementary simplicial collapse is a deformation retract of the polyhedron of the original complex. In order to obtain stratified homotopy equivalence, the particular choice of deformation retraction plays a role. We shall here construct suitable explicit retractions, called freely orthogonal, and investigate their properties. This material is needed only in the proofs of our main results in Section 6.

Let $K$ be a simplicial complex, $p$ a principal simplex of $K$, and $f$ a free face of $p$. With $K'$ denoting the result of the associated elementary collapse, we shall construct a particular deformation retraction

$$H : |K| \times I \longrightarrow |K|$$

onto $|K'|$. Essentially, the idea is to project orthogonally from the free face. Let $v,f_1, \ldots, f_m$ be the vertices of $p$, where the $f_i$ are the vertices of the free face $f$. Let $e_i$ denote the $i$-th standard basis vector of $\mathbb{R}^m$. Identify $v$ with the origin $0 \in \mathbb{R}^m$ and $f_i$ with $e_i$ for all $i = 1, \ldots, m$. Via barycentric coordinates, this identifies $|p|$ with the convex hull of $0,e_1, \ldots, e_m$ in $\mathbb{R}^m$. Under this identification, $|p|$ is given by

$$\{ (x_1, \ldots, x_m) \in \mathbb{R}^m \mid x_i \geq 0, \sum_{i=1}^m x_i \leq 1 \}.$$  

The polyhedron $|f|$ of the free face corresponds to the convex hull of $e_1, \ldots, e_m$,

$$\{ (x_1, \ldots, x_m) \in \mathbb{R}^m \mid x_i \geq 0, \sum_{i=1}^m x_i = 1 \}.$$
The affine hyperplane $H \subset \mathbb{R}^m$ containing the free face is of the form $e_1 + L$, where $L \subset \mathbb{R}^m$ is the linear subspace spanned by the basis $e_2 - e_1$, $e_3 - e_1$, $\ldots$, $e_m - e_1$. Let $\ell$ be the line (through the origin) in $\mathbb{R}^m$ spanned by the vector

$$n = \sum_{i=1}^{m} e_i = (1, 1, \ldots, 1),$$

which is a normal vector to $L$ (with respect to the standard Euclidean inner product on $\mathbb{R}^m$). Let $\partial |p|$ denote the boundary of $|p|$ (i.e. the union of all proper faces) and set

$$\Lambda = \partial |p| - \text{interior} |f|.$$

Thus $\Lambda$ is the union of all intersections of $|p|$ with coordinate hyperplanes $x_j = 0$.

**Lemma 5.1.** For every point $x \in |p|$, the line through $x$ orthogonal to $H$ intersects $\Lambda$ in a unique point $y$, that is, $(x + \ell) \cap \Lambda = \{y\}$.

**Proof.** Given $x = (x_1, \ldots, x_m) \in |p|$ points on $x + \ell$ have the form

$$x + tn = (x_1 + t, \ldots, x_m + t), \ t \in \mathbb{R}. $$

A point of $|p|$ lies in $\Lambda$ precisely when at least one of its coordinates vanishes. So if $y$ is on $x + \ell$ and on $\Lambda$, then one of its coordinates, say $x_j + t$ vanishes, so that $t = -x_j$. Thus

$$y = (x_1 - x_j, x_2 - x_j, \ldots, x_m - x_j).$$

But all of these coordinates must be nonnegative; hence

$$x_j = \min \{x_1, \ldots, x_m\}.$$ 

This shows that $y$, if it exists, is unique. Now for existence, define $y$ by (5) and (4). Then $y$ is plainly on $x + \ell$ and on $\Lambda$. \hfill \Box

Lemma 5.1 shows that there is a well-defined map $r : |p| \rightarrow \Lambda$, $x \mapsto y$. Explicitly, this map is given by

$$r(x_1, \ldots, x_m) = (x_1 - x_j, x_2 - x_j, \ldots, x_m - x_j), \ x_j = \min \{x_1, \ldots, x_m\}.$$ 

This shows that $r$ is continuous. If $x \in \Lambda$, then $x_j = 0$ and thus $r(x) = x$. Thus $r$ is a retraction onto $\Lambda$.

**Lemma 5.2.** If $x \in |p|$ is a point such that $r(x) \in \partial |f|$, then $x \in \partial |f|$.

**Proof.** In terms of coordinates, $\partial |f|$ is characterized by

$$\partial |f| = \Lambda \cap |f| = \{ (x_1, \ldots, x_m) \mid x_i \geq 0, \sum x_i = 1, \text{ and } \exists j : x_j = 0 \}.$$ 

Suppose $x \in |p|$ retracts onto the boundary of $|f|$, i.e. $r(x) \in \partial |f|$. Then the coordinates $(x_1 - x_j, \ldots, x_m - x_j), x_j = \min \{x_i\}$, of $r(x)$ satisfy

$$\sum_{i=1}^{m} (x_i - x_j) = 1,$$

that is,

$$\sum x_i = 1 + mx_j.$$ 

But $x \in |p|$ ensures that $\sum x_i \leq 1$. Consequently, $x_j = 0$. (Note that $m \geq 1$, since $m = \dim p$ and $p$ has a proper face $f$.) This implies that $x \in \Lambda$. Furthermore, it follows that $\sum x_i = 1$, i.e. $x \in |f|$. We conclude that $x \in \Lambda \cap |f| = \partial |f|$. \hfill \Box
Define \( H : |p| \times I \longrightarrow |p| \) to be the straight line homotopy
\[
H(x,t) = (1-t)x + tr(x).
\]
This is well-defined as \(|p|\) is convex. Then \( H \) is a homotopy from \( H_0 = \text{id} \) to \( H_1 = r \) such that
if \( x \in \Lambda \), then \( H(x,t) = (1-t)x + tx = x \), that is, \( H \) is a deformation retraction onto \( \Lambda \). This
\( \Lambda \). This can be readily extended to a deformation retraction
\[
H : |K| \times I \rightarrow |K|
\]
of \( |K| \) onto \( |K'| \) by setting \( H(x,t) = x \) for all \( t \in I \) and all \( x \in |K| - |p| \). We shall refer to this
\( H \) as the freely orthogonal deformation retraction associated to \( p \) and \( f \). Note that all the proper faces of \( f \) are contained in \( \Lambda \). Hence \( H_\Lambda \) is the identity on the proper faces of \( f \).

Let \((K,C,S)\) be a layered simplicial complex.

**Lemma 5.3.** Let \((K,C,S) \searrow (K_S,C,S')\) be an elementary \( S \)-collapse of a principal simplex \( p \in S \) using the free face \( f \in S \). Then the associated freely orthogonal deformation retraction \( H : |K| \times I \rightarrow |K| \) maps
\[
H_t(|K| - |S|) = |K| - |S| \quad \text{and} \quad H_t(|S|) \subset |S|
\]
for all \( t \in I \).

**Proof.** If \( x \in |S| - |p| \), then \( H_t(x) = x \) for all \( t \). If, on the other hand, \( x \in |p| \subset |S| \) then
\( H_t(x) \in |p| \subset |S| \). Hence \( H_t(|S|) \subset |S| \) for all \( t \). Points \( x \in |K| - |S| \) satisfy \( x \in |K| - |p| \), so
that \( H_t(x) = x \). This shows that \( H_t(|K| - |S|) = |K| - |S| \).

**Lemma 5.4.** Let \((K,C,S) \searrow (K_C,C',S)\) be an elementary \( C \)-collapse of a principal simplex \( p \in C \) using the free face \( f \in C \). Then the associated freely orthogonal deformation retraction \( H : |K| \times I \rightarrow |K| \) maps
\[
H_t(|K| - |S|) \subset |K| - |S| \quad \text{and} \quad H_t(|S|) = |S|
\]
for all \( t \in I \).

**Proof.** As \(|p| \subset |C| \) and \(|S| \cap |C| = \emptyset \), the complex \(|S| \) is contained in \(|K| - |p| \), on which \( H_\Lambda \)
is the identity for all \( t \). We conclude that \( H_t(|S|) = |S| \). If \( x \in |K| - (|S| \cup |p|) \), then again \( H_t(x) = x \in |K| - |S| \). If, on the other hand, \( x \in |p| \subset |K| - |S| \), then \( H_t(x) \in |p| \subset |K| - |S| \).

**Lemma 5.5.** Let \((K,C,S)\) be the associated layered complex of a divided complex \((K,S')\). Let \((K,C,S) \searrow (K_t,C,S)\) be an elementary intermediate collapse of a principal simplex \( p \in \text{IM}(K,C,S) \) using the free face \( f \). Then the associated freely orthogonal deformation retraction \( H : |K| \times I \rightarrow |K| \) maps
\[
H_t(|K| - |S|) \subset |K| - |S| \quad \text{and} \quad H_t(|S|) \subset |S|
\]
for all \( t \in I \).

**Proof.** We shall first show that
\[
|S| \cap |p| \subset \partial |f|.
\]
Indeed, given a point \( x \in \partial |S| \), there is a unique face \( s \in S \) of \( p \) that contains \( x \) in its interior.
This face must be a proper face of \( p \), since if \( s = p \), then \( p \in S \), contradicting \( p \in \text{IM}(K,C,S) \). By
condition (iv) for intermediate collapses, \( s \) is a proper face of \( f \). Hence \( x \in |s| \subset \partial |f| \), establishing (6).

As \( \partial |f| \subset \Lambda \) and \( r \) is a retract onto \( \Lambda \), it follows in particular that \( r(x) = x \) for points \( x \in \partial |S| \) and hence that \( H_t(x) = (1-t)x + tr(x) = x \) for such \( x \) and all \( t \). So \( H_t(|S| \cap |p|) \subset |S| \) for all \( t \). If \( x \in |S| - |p| \), then \( H_t(x) = x \in |S| \) by definition. This proves \( H_t(|S|) \subset |S| \) for all \( t \).
It remains to verify \( H_t([K] - |S|) \subset |K| - |S| \). Let \( x \) be a point in \(|K| - |S|\). If \( x \notin |p| \), then \( H_t(x) = x \in |K| - |S| \). So suppose that \( x \in |p| \). If \( r(x) = x \), then again \( H_t(x) = x \) and we are done. So assume that \( r(x) \neq x \). Suppose it were then true that \( r(x) \in |S| \). Then \( r(x) \in |p| \cap |S| \) and hence \( r(x) \in \partial |f| \) by \( \text{(6)} \). Lemma \( \text{[5.2]} \) implies that \( x \in \partial |f| \). As \( \partial |f| \subset \Lambda \) and \( r \) is a retract onto \( \Lambda \), we deduce that \( r(x) = x \), contradicting \( r(x) \neq x \). Therefore \( r(x) \notin |S| \). Thus \( H_t(x) \notin |S| \) for \( t = 0,1 \).

We claim that if \( t > 0 \), then \( H_t(x) \notin |f| \). By contradiction: Suppose \( (1-t)x + tr(x) \in |f| \), so that

\[
\sum_i ((1-t)x_i + tr(x_i)) = 1, \quad x_j = \min\{x_1, \ldots, x_m\}.
\]

Note that \( x_j > 0 \), since we know that \( x \notin \Lambda \) (as \( r(x) \neq x \)). It follows that

\[
\sum_i x_i = 1+mx_j.
\]

Since \( t > 0 \), \( m \geq 1 \) and \( x_j > 0 \), this implies \( \sum x_i > 1 \), contradicting \( \sum x_i \leq 1 \) (\( x \in |p| \)). Thus \( H_t(x) \notin |f| \) as claimed. Now if \( H_t(x) \) were in \(|S| \) for \( t > 0 \), then it would have to be in \( \partial |f| \subset |f| \) by \( \text{(6)} \), which we have just proved to be impossible. Hence \( H_t(x) \notin |S| \), as was to be shown. \( \square \)

6. Stratified Formal Deformations, Homotopy Type and Intersection Homology

Our main result relates the layered formal deformation type of a complex to the stratified homotopy type of associated filtered spaces. As a corollary, we conclude that the intersection homology is preserved by layered formal deformations. In particular, the intersection homology of any two stratified spines (which may well not be homeomorphic) will be isomorphic. Recall that for ease of exposition we will illustrate our results only for filtrations of type \( \text{(1)} \).

**Lemma 6.1.** Let \((K,S)\) and \((K',S')\) be the associated layered simplicial complexes of divided simplicial complexes, and suppose that the polyhedra \(X = |K|\) and \(X' = |K'|\) are filtered spaces with respective singular sets \(\Sigma = |S|\), \(\Sigma' = |S'|\) whose formal codimensions coincide, \(\text{codim}_X \Sigma = \text{codim}_{X'} \Sigma'\). If \((K',S')\) is obtained from \((K,S)\) by an elementary layered collapse, then \((X,\Sigma)\) and \((X',\Sigma')\) are stratified homotopy equivalent.

**Proof.** Let \((K,S) \searrow (K',S')\) be an elementary layered collapse of a principal simplex \(p\) using the free face \(f\) of \(p\). Let \(H : |K| \times I \to |K|\) be the freely orthogonal deformation retraction associated to \(p\) and \(f\), satisfying \(H_t([K]) \subset [K']\); on \(|p|\), \(H_1\) is given by the retraction \(r\) of Section \(\text{[5]}\). We claim that the inclusion

\[
(|K'|,|S'|) \hookrightarrow (|K|,|S|)
\]

is a stratified homotopy equivalence with stratified homotopy inverse

\[
(|K|,|S|) \xrightarrow{r} (|K'|,|S'|).
\]

To prove the claim, we establish first that both \(i\) and \(r = H_1\) are codimension-preserving stratified maps. First, a preliminary remark. In the case of an \(S\)-collapse,

\[
S' = K' \cap S
\]

by \(\text{(2)}\); in the case of a \(C\)-collapse, \(S' = S\). The latter equality holds also in the case of an intermediate collapse, by Lemma \(\text{[5.7]}\). When \(S' = S\), then \(K' \cap S = K' \cap S' = S'\). Hence \(\text{(7)}\) holds in all three cases. Now the inclusion \(i : |K'| \hookrightarrow |K|\) maps \(|S'|\) to \(|K'| \cap |S'|\). Using \(\text{(7)}\),

\[
|K| \cap |S'| = |K| \cap |K'| \cap |S| \subset |S|,
\]

and
so \( i \) maps the singular sets correctly. Since \( H_i(|K|) \subset |K'| \), and \( H_i(|S|) \subset |S| \) for all \( t \), we have
\[
r(|S|) \subset |K'| \cap |S| = |S'|,
\]
so \( r \) maps the singular sets correctly as well.

If \( x \in |K'| - |S'| \), then \[\Box\] shows that \( x \notin |S| \). Thus \( i(|K'| - |S'|) \subset |K| - |S| \) as claimed. Let \( x \) be a point in \( |K| - |S| \), and suppose that \( r(x) \in |S'| \). Then \[\Box\] shows that \( r(x) \in |S| \).

But by Lemmas \[\Box\] and \[\Box\] \( r(x) = H_t(x) \in |K| - |S| \), a contradiction since \( |S| \subset |K| \).

Thus \( r(x) \notin |S'| \) so that \( r(|K| - |S|) \subset |K'| - |S'| \) as required. We have shown that \( i \) and \( r \) are stratified maps. They are codimension-preserving by assumption.

Since \( r \) is a retraction, \( r \circ i = \text{id}_{|K'|} \). It remains to be shown that \( i \circ r \) is stratified homotopic to the identity on \( |K| \). A stratified homotopy is given by the above freely orthogonal deformation retraction \( H \): By Lemmas \[\Box\] \[\Box\] and \[\Box\] \( H \) maps \( |S| \times I \) into \( |S| \) and \( (|K| - |S|) \times I \) into \( |K| - |S| \) in all three cases \( (S, \cdot, \cdot) \) and \( (K, C, S) \).

\( \square \)

**Theorem 6.2.** Let \((K, C, S)\) and \((K', C', S')\) be the associated layered simplicial complexes of divided simplicial complexes, and suppose that the polyhedra \( X = |K| \) and \( X' = |K'| \) are filtered spaces with respective singular sets \( \Sigma = |S| \), \( \Sigma' = |S'| \) whose formal codimensions coincide, \( \text{codim}_X \Sigma = \text{codim}_X \Sigma' \). If there exists a layered formal deformation between \((K, C, S)\) and \((K', C', S')\), then \((X, \Sigma)\) and \((X', \Sigma')\) are stratified homotopy equivalent.

**Proof.** Let
\[
(K, C, S) = (K_0, C_0, S_0) \rightarrow (K_1, C_1, S_1) \rightarrow \cdots \rightarrow (K_m, C_m, S_m) = (K', C', S')
\]
be a layered formal deformation between \((K, C, S)\) and \((K', C', S')\), where each arrow indicates an elementary layered collapse or layered expansion. The polyhedral pair \((X_i, \Sigma_i) := (|K_i|, |S_i|), i = 0, \ldots, m, \) becomes a filtered space by declaring the formal codimensions of the singular sets to be \( \text{codim}_X \Sigma_i := \text{codim}_X \Sigma \). Then Lemma \[\Box\] is applicable to \((K_0, C_0, S_0) \rightarrow (K_{i+1}, C_{i+1}, S_{i+1})\) and yields a stratified homotopy equivalence \((X_i, \Sigma_i) \simeq (X_{i+1}, \Sigma_{i+1})\) for every \( i = 0, \ldots, m - 1 \). The composition of these stratified homotopy equivalences is a stratified homotopy equivalence
\[
(X, \Sigma) = (X_0, \Sigma_0) \simeq (X_m, \Sigma_m) = (X', \Sigma')
\]
by Lemma \[\Box\] \( \square \)

As a special case of the theorem, we deduce that any two stratified spines of a layered complex lie in the same classical stratified homotopy type:

**Corollary 6.3.** Let \((K, C, S)\) be the associated layered simplicial complex of a divided simplicial complex. If \((K', C', S')\) and \((K'', C'', S'')\) are layered spines of \((K, C, S)\) whose polyhedra \( X = |K| \) and \( Y = |K''| \) are filtered spaces with respective singular sets \( \Sigma_X = |S'| \), \( \Sigma_Y = |S''| \) whose formal codimensions coincide, then the stratified spines \((X, \Sigma_X)\) and \((Y, \Sigma_Y)\) are stratified homotopy equivalent.

**Theorem 6.2** has the following consequence for the combinatorial deformation stability of singular intersection homology:

**Corollary 6.4.** Let \((K, C, S)\) and \((K', C', S')\) be the associated layered simplicial complexes of divided simplicial complexes, and suppose that the polyhedra \( X = |K| \) and \( X' = |K'| \) are filtered spaces with respective singular sets \( \Sigma = |S| \), \( \Sigma' = |S'| \) whose formal codimensions coincide. If there exists a layered formal deformation between \((K, C, S)\) and \((K', C', S')\), then \( IH^p(X) \cong IH^p(Y) \) for every \( p \).

**Proof.** This follows from Theorem \[\Box\] in view of Proposition \[\Box\] \( \square \)
To compute the singular intersection homology groups algorithmically via simplicial intersection chains, one may use Propositions 3.12 and 3.14. From the point of view of a given filtered Vietoris-Rips type complex \( K \) associated to data points near a filtered space \( X \), our results lead to conditions under which the complex \( K \) itself can be used to compute the intersection homology of \( X \):

**Corollary 6.5.** Let \((K, S^0)\) be a divided simplicial complex and \((X, \Sigma)\) a filtered space. (In practice, \( K \) could be a Vietoris-Rips, Čech, etc. type complex associated to points near \( X \), with points of \( S^0 \) near \( \Sigma \).) If there exists a layered formal deformation from the associated layered complex \((K, C, S)\) to a layered complex \((K', C', S')\) whose filtered space \(|K'|, |S'|\), with \(\text{codim}|S'| = \text{codim}_X \Sigma \) is stratified homotopy equivalent to \((X, \Sigma)\), then, taking formal codimension \(\text{codim}_{K'}|S'| = \text{codim}_X |S'|\), the intersection homology of the filtered space \(|K|, |S|\) computes the intersection homology of \((X, \Sigma)\).

As pointed out earlier, these codimensions are not a priori known, but may in fact be revealed by spines. The corollary shows in particular that if a Vietoris-Rips type complex \( K \) has a stratified spine which is, say, stratified homeomorphic to \( X \), then \(\text{IH}^p(X)\) may already be computed from \(\text{IH}^p(K)\) by using the appropriate codimension.

7. Implementation

Given a set of data points, we used standard Delaunay-Vietoris-Rips methods to generate simplicial complexes, but our stratified collapse methods are applicable to any filtered polyhedron and thus one could in addition investigate the behavior of Čech complexes, witness complexes, etc. The Delaunay-Vietoris-Rips complex is the restriction of the Vietoris-Rips complex to simplices of the Delaunay triangulation. Using Delaunay triangulations to generate simplicial complexes from sets of data points is a common approach in topological data analysis, see e.g. [11], [9], [3]. To illustrate stratified formal deformations, we focus here on stratified spines. A possible pseudocode sequencing of the three types of elementary layered collapse operations is shown in Algorithm 7.1. The code blocks 1–3 and 4–6 can be inter-

**Algorithm 7.1 LayeredSpine(K, C, S)**

**Input:** \((K, C, S)\) layered complex of a divided simplicial complex  
**Output:** \((K, C, S)\) layered complex with no further layered collapses possible  
1. **while** \( S \)-collapse possible in \((K, S)\) **do**  
2. \hspace{1em} \((K, S) \leftarrow \text{Collapse}(K, S)\)  
3. **end while**  
4. **while** \( C \)-collapse possible in \((K, C)\) **do**  
5. \hspace{1em} \((K, C) \leftarrow \text{Collapse}(K, C)\)  
6. **end while**  
7. \( IM \leftarrow \text{IntermediateSimplices}(K, C, S) \)  
8. **while** intermediate collapse possible in \((K, IM, S)\) **do**  
9. \hspace{1em} \((K, IM) \leftarrow \text{IMCollapse}(K, IM, S)\)  
10. **end while**  
11. **while** \( C \)-collapse possible in \((K, C)\) **do**  
12. \hspace{1em} \((K, C) \leftarrow \text{Collapse}(K, C)\)  
13. **end while**  
14. **return** \((K, C, S)\)
changed, as \(S\)-collapses and \(C\)-collapses are commuting operations. This shows in particular that after step 6, no new \(S\)-collapses can become possible. After step 10, no \(S\)-collapses can become possible by Proposition 4.15. But \(C\)-collapses may become possible after intermediate collapses, as Example 4.16 shows. Hence the code block 11–13 is required. After step 13, no \(S\)-collapse can be possible, for if it were, then it could be commuted to be executed between line 10 and 11, but we already know that after step 10, no \(S\)-collapse is possible. Furthermore, after step 13, no intermediate collapse is possible by Proposition 4.17. Therefore, after step 13, the resulting layered simplicial complex is in fact a layered spine. In step 7, the set \(IM\) of intermediate simplices of \((K, C, S)\) is computed, which is straightforward — include all simplices of \(K\) that have at least one vertex in \(S\) and at least one vertex in \(C\). According to Lemma 4.6, \(IM\) can be computed earlier, but it is of course advantageous to compute it as late as possible, since the previous collapses reduce the search space. The function \(\text{Collapse}(K, L)\) executes elementary collapses in \(K\) only of simplices contained in a subcollection \(L \subset K\). This is suited for \(S\)- and \(C\)-collapses. Intermediate collapses require a different treatment, detailed in Algorithm 7.2. We included only the pseudocode for intermediate collapses. For \(S\)- and \(C\)-collapses the code looks almost identical, excluding step 5, which tests condition (iv) of an intermediate collapse by calling the function \(\text{isAdmissible}(S, S, p[0])\). Algorithm 7.2 makes implicit use of the fact, established earlier (in Lemmas 4.7 and 4.8), that a free face of any coface (in particular a principal one) of an intermediate simplex such that (iv) holds must itself be intermediate. Conversely, any coface (in particular a principal one) of an intermediate simplex is obviously intermediate itself. The function \(\text{Princ}(IM, s, K)\) searches for cofaces in \(IM\) of a simplex \(s\) that are principal in \(K\). (By the previous remark, one need not search in all of \(K\), only in \(IM\).) If it finds none or more than one, it returns the empty list, otherwise a list \(p\) of length 1 containing the unique principal coface \(p[0]\) (in which case \(s\) is free). If desired, it is after execution of 7.1 algorithmically possible to check whether the polyhedron of the layered spine is a pseudo-manifold: Let \(n\) be the highest dimension of a simplex in the complex. Then check whether every \((n - 1)\)-simplex is the face of precisely two \(n\)-simplices and whether every simplex is the face of some \(n\)-simplex.

Furthermore, there exist algorithms to compute (simplicial) intersection homology, even persistent intersection homology, \[4,20\]. We followed these to code the calculation of simplicial intersection Betti numbers. Persistent intersection homology has been implemented by Bastian Rieck in his \texttt{Aleph} package. In principle, calculating intersection homology groups uses the same matrix operations that may be used to compute ordinary simplicial homology. The difference lies in the process that sets up the simplicial intersection chain complex. The definition of \(IC^\mathbb{Z}_p(-) \subset C_*(-)\) requires us to check which simplicial chains are \(\bar{p}\)-allowable for a given perversity \(\bar{p}\). Note that it is not enough to verify allowability on the simplex level because we want to identify all \(\bar{p}\)-allowable simplicial chains. We describe an algorithm that can be used to generate the intersection chain complex from a given simplicial chain complex. This is taken from \[43\] in which an algorithm was introduced to compute persistent intersection homology with \(\mathbb{Z}_2\) coefficients. We will here only describe those parts of the algorithm that solve the problem of identifying the intersection chains.

Let \(K\) be a simplicial complex and \(\bar{p}\) be an arbitrary perversity. Note that we are over \(\mathbb{Z}_2\) and thus orientations are not an issue. Let \(IS^\bar{p}_k(K)\) denote the collection of all \(\bar{p}\)-allowable \(k\)-simplices of \(K\). Next, for every \(k\), we choose an ordering of \(IS^\bar{p}_k(K)\) such that \(IS^\bar{p}_k(K) = \{ \sigma_0^{(k)}, \ldots, \sigma_k^{(k)}, \sigma_{k+1}^{(k)}, \ldots, \sigma_m^{(k)} \}\), where \(\sigma_0^{(k)}, \ldots, \sigma_k^{(k)}\) are all \(\bar{p}\)-allowable \(k\)-simplices of \(K\).
Algorithm 7.2 IMCollapse\((K, IM, S)\)

**Input:** \(K\) simplicial complex, \(S\) subcomplex of \(K\), \(IM\) intermediate simplices

**Output:** \(K\) simplicial complex, \(IM\) intermediate simplices

1: \(I \leftarrow IM\)
2: for \(s\) in \(I\) do
3: \(p \leftarrow \text{Princ}(IM, s, K)\)
4: if nonempty\((p)\) then
5: if isAdmissible\((S, s, p[0])\) then
6: Remove \(p[0]\) from \(K\)
7: Remove \(p[0]\) from \(IM\)
8: Remove \(s\) from \(K\)
9: Remove \(s\) from \(IM\)
10: \(\triangleright\) At this point, the new \(IM\) is indeed the set
11: \(\triangleright\) of intermediate simplices of the new \(K\) by \(\{3\}\).
12: end if
13: end if
14: end for
15: return \((K, IM)\)

Set up an incidence matrix \(M\) over \(\mathbb{Z}_2\) with entries

\[
\begin{align*}
M_{ij} &= 1, \text{ if } \sigma_i^{(k-1)} \text{ is a face of } \sigma_j^{(k)}, \\
M_{ij} &= 0, \text{ else},
\end{align*}
\]

\(i = 0, \ldots, m_{k-1}, j = 0, \ldots, r_k\). The columns that have nonzero entries below the \(r\)-th row represent \(\overline{p}\)-allowable \(k\)-simplices whose boundaries contain not \(\overline{p}\)-allowable \((k-1)\)-simplices and therefore do not represent a \(\overline{p}\)-allowable elementary chain. By elementary column transformations from left to right, we want to reduce as much of the rows below \(r\) as possible to form allowable chains. This is done by adding up columns with the same value in rows with higher index than \(r\). The pseudocode of Algorithm 7.3 describes how this reduction can be realized on a computer. The function \(\text{low}(M, j)\) returns the index of the lowest nonzero entry

Algorithm 7.3 MatrixReduction\((M, r)\)

**Input:** \(M\) binary incidence matrix, \(r\) row index

**Output:** \(M\) matrix in reduced form

1: \(ncol \leftarrow \text{length}(M[0,:])\) \(\triangleright\) Number of columns
2: for \(j := ncol - 1\) downto 1 do
3: \(\text{while } \exists i < j \text{ with low}(M, i) = \text{low}(M, j) \text{ and low}(M, j) > r\) do
4: \(M[:,j] \leftarrow M[:,j] + M[:,i]\)
5: end while
6: end for
7: return \(M\)

in the \(j\)-th column of a given matrix \(M\), in case it exists. The function returns \(-1\), if the column only contains zeros. Furthermore, it is possible to record the column transformations executed during a reduction process to determine a basis for the intersection chain complex in every degree. Now, deleting all columns \(i\) in \(M\) with \(\text{low}(M, i) > r\) and all rows below
one obtains matrices whose ranks can be used to calculate the intersection Betti numbers.
Our Python code, both for the computation of stratified spines and intersection Betti numbers,
is available at https://github.com/BanaglMaeder/layered-spines.git. It was not our first priority to optimize the code for efficiency, and certainly several refinements in this direction are possible.

8. Examples and Evaluation

We illustrate stratified formal deformations and associated intersection homology groups by algorithmically computing several stratified spines of Vietoris-Rips type complexes associated to data point samples near given spaces. Our first example concerns the cone on a circle. Such a cone is topologically a 2-disc and thus nonsingular, but when filtered by the cone-vertex and using appropriate perversities, may nevertheless have nonvanishing intersection homology in positive degrees.

**Example 8.1.** As an implicit surface, the cone on $S^1$ is given by
$$\text{cone}(S^1) = \{ (x, y, z) \in \mathbb{R}^3 \mid x^2 + y^2 = c^2(z-1)^2 \text{ and } 0 \leq z \leq 1 \}$$
with $c$ being the base/height ratio of the cone; the cone vertex is $s = (0, 0, 1)$. When filtered by the cone vertex of codimension 2, the cone has intersection homology $\text{IH}^0_\ast(\text{cone } S^1; \mathbb{Z}_2) = \{ \mathbb{Z}_2, \text{ if } i = 0 \}$ and $\text{IH}^1_\ast(\text{cone } S^1; \mathbb{Z}_2) = \{ \mathbb{Z}_2, \text{ if } i = 0, 1 \}$.

(Recall that we write $\mathbb{Z}_2 = \mathbb{Z}/2\mathbb{Z}$.) Choosing $c = 3$, we then produced a set of 34 random points in $\mathbb{R}^3$ by rejection sampling. In more detail, independent sampling of two uniformly distributed points on the interval $[-1, 1]$ for the $x$- and $y$-coordinate and on the interval $[0, 1]$ for the $z$-coordinate yields a triple $(x, y, z) \in \mathbb{R}^3$. If such a point satisfied the equation that defines the cone up to an error of 0.001, we accepted that point as part of our sample. The cone vertex $s$ is part of the sample as well. Applying Vietoris-Rips type methods, we generated a 3-dimensional simplicial complex $K$ with polyhedron $X = |K|$ depicted in Figure 4. Taking $S^0 = \{ s \}$ endows $K$ with the structure of a divided complex. Using the natural geometric codimension $\text{codim}\{s\} = 3$ in the 3-dimensional polyhedron $X$, the intersection homology is given by

$$\text{IH}^0_\ast(X; \mathbb{Z}_2) = \begin{cases} \mathbb{Z}_2, & \text{ if } i = 0, 1 \\ 0, & \text{ else.} \end{cases}$$

$$\text{IH}^1_\ast(X; \mathbb{Z}_2) = \begin{cases} \mathbb{Z}_2, & \text{ if } i = 0, 1 \\ 0, & \text{ else.} \end{cases}$$

which does not agree with the above intersection homology of the underlying cone.

A stratified spine $(X', \Sigma' = S^0)$ of $(X, \Sigma = S^0)$ is shown in Figure 5. Using the algorithms described in Section 7, this stratified spine was obtained on a computer by carrying out 93 elementary $C$-collapses and 4 elementary intermediate collapses. Note that the stratified spine is in fact stratum-preserving homeomorphic to the cone on $S^1$, which implies in particular that the intersection homology of the stratified spine agrees with the above intersection homology of $\text{cone}(S^1)$ (which can also be algorithmically verified.) Performing further unrestricted collapses on the stratified spine would show that an ordinary spine of $X$ is a point. This shows
that \( X \) is (simple) homotopy equivalent to the cone on \( S^1 \). So the ordinary spine does not preserve enough structure to carry the correct intersection homology. The stratified spine contains substantially fewer simplices than \( K \) and so the linear algebra packages performing rank computations to determine the intersection homology can operate on substantially smaller matrices. We find that computing spines first is often a way to avoid sparse matrix techniques altogether. In light of our invariance results, Corollaries 6.3 and 6.4, the discrepancy between the intersection homology of the Vietoris-Rips polyhedron \( X \) and the intersection homology of the stratified spine is due to the discrepancy between the codimensions of the singular point. Thus computing stratified spines is in particular a way of obtaining better estimates of correct codimensions.

The next example deals with a much larger dataset on a pinched torus.

**Example 8.2.** Topologically, the pinched torus is the quotient space of the torus \( T^2 = S^1 \times S^1 \) obtained by collapsing a circle \( pt \times S^1 \). The image of this circle is the singular point \( s \) of the pinched torus. Points were sampled from an embedded pinched torus. We sampled independently a pair of identically uniformly distributed points on the interval \([0, 2\pi]\). Then a parametrization of the surface was used to transform the sample to lie on the pinched torus. Applying Vietoris-Rips methods resulted in a simplicial complex \( K \) with 543 0-simplices, 2109 1-simplices, 2057 2-simplices and 490 3-simplices. Figure 6 shows the polyhedron \( X = |K| \) of this complex. Figure 7 shows the volume of all 490 3-simplices. Putting \( S^0 = \{s\} \) endows \( K \) with the structure of a divided simplicial complex. The polyhedron \( X \) of the associated layered complex \((K, C, S = S^0)\) is filtered by \( \Sigma = \{s\} \). A stratified spine \( X' \) of \( X \) was determined algorithmically and is displayed in Figure 9. This computation comprised 978 elementary \( C \)-collapses and 11 elementary intermediate collapses. Figure 8 shows an intermediate stage in the process of determining the stratified spine. At that point, all \( C \)-collapses have been executed and the next step is collapsing all intermediate simplices as far as possible. After the whole process, all 3-simplices initially present have been removed and the overall size of the simplicial complex has been reduced to 537 0-simplices, 1610 1-simplices and 1074 2-simplices. The stratified spine \( X' \) is filtered by \( |S^0| = X^0 \subset X^2 = X' \) and therefore simplicial intersection homology groups are defined. Using our implementation, we obtain for perversity \( 0 \) simplicial intersection homology of the stratified spine:

\[
IH_0^\delta(X'; \mathbb{Z}_2) = \begin{cases} 
\mathbb{Z}_2, & \text{if } i = 0, 2 \\
0, & \text{else.}
\end{cases}
\]
These results agree with the singular perversity $0$ intersection homology of the actual pinched torus. They also agree with the intersection homology of the full Vietoris-Rips polyhedron $X$, both when $\{s\}$ is assigned formal codimension 3 (the geometric codimension in $K$) and when it is assigned formal codimension 2 (the geometric codimension in the stratified spine).
Example 8.3. We may return to the figure eight space $S^1 \vee S^1$ of Example 3.15 and reconsider it from the stratified spinal point of view. The (ordinary) spine $X'$ shown in Figure 2 is in fact also a stratified spine of $X$. The green 2-simplex in the lower left of Figure 1 is removed by an elementary $C$-collapse, while the other two green 2-simplices, incident to the singular point, are removed by elementary intermediate collapses. So here the stratified spine happens to be stratified homeomorphic to the ordinary spine and both compute the intersection homology of $S^1 \vee S^1$. 
Finally, it is clear that the Vietoris-Rips method (and similar methods) may create local thickenings near the singularities that cannot be removed by stratified collapses to an extent that would make the stratified homotopy type of the original space, or at least its intersection homology, visible. An example polyhedron $X$ obtained by sampling two tangent circles, topologically comprising $S^1 \vee S^1$, is shown in Figure 10. Finding general characterizations of such configurations, as well as, perhaps even more importantly, improving the Vietoris-Rips method in stratified situations, is an interesting question that requires methods outside the scope of the present paper. It is perhaps interesting to observe that $X$ contains an ordinary spine $X'$, shown in Figure 11, which is stratified homeomorphic to $S^1 \vee S^1$. One could interpret this as an indication that there exist further types of intermediate collapses. These may be formulated and explored in future work. Furthermore, if one is merely interested in intersection homology $IH_{\bar{p}}^*$ for a particular perversity $\bar{p}$, then one might expect to obtain a relaxed perversity-dependent version of the intermediate collapse condition (iv).
