Abstract

Using the HERA-B detector, the $b\bar{b}$ production cross section has been measured in 920 GeV proton collisions on carbon and titanium targets. The $b\bar{b}$ production was tagged via inclusive bottom quark decays into $J/\psi$ by exploiting the longitudinal separation of $J/\psi \rightarrow l^+l^-$ decay vertices from the primary proton-nucleus interaction. Both $e^+e^-$ and $\mu^+\mu^-$ channels have been reconstructed and the combined analysis yields the cross section $\sigma(b\bar{b}) = 32^{+14}_{-12}(\text{stat})^{+6}_{-7}(\text{sys})$ nb/nucleon.

Key words: hadroproduction, bottom mesons

PACS: 13.85.Ni 13.85.Qk 13.20.He 24.85.+p
1 Introduction

The theoretical description of heavy quark hadroproduction has been a subject of great attention in recent years [1–4]. For fixed target experiments [2,3], the predictions, based on perturbative QCD, are compatible with experimental results from pion and proton beams, but both theoretical and experimental uncertainties are large. Only two measurements of the $b\bar{b}$ production cross section in proton-nucleus $p + A$ interactions were previously reported [5,6]. Moreover, in collider experiments, the comparison between data and QCD predictions is not satisfactory [4].

The HERA – B experiment is designed to identify B-meson decays in a dense hadronic environment, with a large geometrical coverage. Interactions are produced on target wires in the halo of the 920 GeV HERA proton beam. The $b\bar{b}$ production cross section ($\sigma_A^B$) on a nucleus of atomic number $A$ is obtained from the inclusive reaction

$$pA \to b\bar{b} X \quad \text{with} \quad b\bar{b} \to J/\psi Y \to (e^+e^-/\mu^+\mu^-)Y.$$  \hspace{1cm} (1)

The $b$-hadron decays into $J/\psi$ (“$b \to J/\psi$” in the following) are distinguished from the large prompt $J/\psi$ background by exploiting the $b$ lifetime in a detached vertex analysis. We select $b \to J/\psi \to l^+l^-$ decays in both the muon and electron channels and perform a combined $b\bar{b}$ production cross section measurement.

In order to minimize the systematic errors related to detector and trigger efficiencies and to remove the dependence on the absolute luminosity determination, the measurement is performed relative to the known prompt $J/\psi$ production cross section $\sigma_P^A$ [7,8]. Our measurement covers the $J/\psi$ Feynman- $x$ ($x_F$) range $-0.25 \leq x_F \leq 0.15$. Within our acceptance, the $b$ to prompt cross section ratio can be expressed as:

$$\frac{\Delta \sigma_B^A}{\Delta \sigma_P^A} = \frac{N_B}{N_P} \frac{1}{\varepsilon_R \varepsilon_{B}^{\Delta z} \text{Br}(b\bar{b} \to J/\psi X)},$$  \hspace{1cm} (2)

where $\Delta \sigma_B^A$ and $\Delta \sigma_P^A$ are the $b \to J/\psi$ and prompt $J/\psi$ cross sections limited to the mentioned $x_F$ range, $N_B$ and $N_P$ are the observed number of detached $b \to J/\psi$ and prompt $J/\psi$ decays, $\varepsilon_R$ is the relative detection efficiency of $b \to J/\psi$ with respect to prompt $J/\psi$, including contributions from the trigger, the dilepton vertex and the $J/\psi$ reconstruction, $\varepsilon_{B}^{\Delta z}$ is the efficiency of the detached vertex selection. The branching ratio $\text{Br}(b\bar{b} \to J/\psi X)$ in hadroproduction is assumed to be the same as that measured in $Z$ decays, with the value $2 \cdot (1.16 \pm 0.10)\%$ [9].
The prompt $J/\psi$ production cross section per nucleon, $\sigma(pN \to J/\psi X) = \sigma^A_p/A^\alpha$, was previously measured by two fixed target experiments [7,8]. After correcting for the most recent measurement of the atomic number dependence ($\alpha = 0.955 \pm 0.005$ [10]) and rescaling [11] to the HERA-B c.m.s. energy, $\sqrt{s} = 41.6$ GeV, we obtain a reference prompt $J/\psi$ cross section of $\sigma(pN \to J/\psi X) = (357 \pm 8{\text{ (stat)}} \pm 27{\text{ (sys)}})$ nb/nucleon. About 70% [7] of the $J/\psi$ are produced in the kinematic range covered by our measurement.

Since no nuclear suppression has been observed in $D$-meson production [12] and a similar behavior is expected in the $b$ channel [13], we assume $\alpha = 1.0$ for the $b\bar{b}$ production cross section results presented here; i.e., $\sigma^A_B = \sigma(pN \to b\bar{b}) \cdot A$.

2 Detector, Trigger and Data sample

A side view of the HERA-B [14,15] spectrometer is shown in Fig. 1. The spectrometer has a large geometrical coverage, from 15 mrad to 220 mrad in the bending plane and from 15 mrad to 160 mrad in the vertical plane.

The target assembly [16] consists of two wire stations separated by 4 cm along the beam line, each containing 4 target wires of different materials. A servo system automatically steers the target wires during a run in order to maintain a constant interaction rate. The Vertex Detector System (VDS) [17] is realized by a system of 20 Roman pots containing seven planar stations (4 stereo views) of double-sided silicon micro-strip detectors (50 mm × 70 mm sensitive area, 50 µm pitch) that are operated in a vacuum vessel at 10 to 15 mm distance from the proton beam. An additional station is mounted immediately behind the 3 mm thick Al window of the vacuum vessel.
A dipole magnet with 2.13 Tm field-integral houses a first set of tracking stations, followed by a second set extending to 13 m downstream of the interaction region. To cope with the large particle flux gradient radial to the beam, the tracker is divided into a fine grained Inner Tracker (ITR) [18] and a large area Outer Tracker (OTR) [14,19]. The ITR uses micro-strip gas chambers (typical pitch of 300 µm) with gas electron multipliers. The OTR uses honeycomb drift cells with wire pitches of 5 mm near the beam and 10 mm away from the beam.

The particle identification is performed by a ring imaging Cherenkov hodoscope (RICH) [20], an electromagnetic calorimeter (ECAL) [21] and a muon detector (MUON) [22]. The RICH detector uses C_4F_{10} as radiator. The focal planes of the detector (above and below the beam line, respectively) are read out by multianode photomultipliers. The ECAL is based on “shashlik” sampling calorimeter technology, consisting of scintillator layers sandwiched between metal absorbers. In the radially innermost section, W is used in the absorber, and Pb everywhere else. The MUON system consists of 4 tracking stations located in the most downstream portion of the detector, at different depths in iron and iron-loaded absorbers. It is built from gas-pixel chambers in the radially innermost region and from proportional tube chambers, some with segmented cathodes (pads), everywhere else.

The data sample presented in this analysis was acquired in a short physics run during the HERA - B commissioning period in summer 2000, at ≈5 MHz interaction rate, with a maximum of two target wires operated simultaneously and separated by 4 cm along the beam direction. The two wires were made of carbon (1000 µm longitudinally and 100 µm transversely) and titanium (500 µm and 50 µm, respectively).

The data were collected by triggering on dimuon and dielectron signatures. The MUON pretrigger candidates were based on a double pad chamber coincidence [23], while the ECAL pretrigger candidates were defined by ECAL clusters with a transverse energy $E_T > 1.0$ GeV [24]. The First Level Trigger (FLT) required two pretrigger candidates of the same type and forwarded these to the Second Level Trigger (SLT). The SLT is a software filter [25] running on a farm of 240 PCs. Starting from the pad coincidences and high-$E_T$ ECAL clusters, a fast hit-counting algorithm and a simplified Kalman filter were applied to the OTR and VDS data to confirm the lepton pair candidates. An invariant mass cut of $M > 2.0$ GeV/$c^2$ and an unlike-sign track requirement were also applied in the electron channel. The data from accepted events were assembled and sent to the online reconstruction farm [26], consisting of 100 dual-CPU PCs. The whole trigger chain allowed a reduction of the initial interaction rate of 5 MHz to a final output rate of 20 Hz [27]. A total of ≈450,000 dimuon and ≈900,000 dielectron candidates were recorded under these conditions.
At the time of data taking, the ITR and the MUON pixel chambers were not included in the trigger. As a consequence, the forward hemisphere of the proton-nucleus c.m.s. is reduced in this measurement, compared to the full HERA-B acceptance.

3 Monte Carlo Simulation

A Monte Carlo (MC) simulation is used to determine the efficiency terms in Eq. 2 and to estimate the prompt $J/\psi$ background contribution to the $b \to J/\psi$ decay channel.

The simulation of heavy quark ($Q$) production is achieved, first, by generating the basic process $pN \to Q\bar{Q}X$ including hadronization, using the PYTHIA 5.7 event generator [28]; secondly, the remaining part of the process ($X$) is given as an input to the Fritiof 7.02 package [29] to simulate further interactions inside the nucleus.

To describe the prompt $J/\psi$ kinematics accurately, the generated events are weighted according to the known prompt $J/\psi$ differential cross sections ($d\sigma/dp_T^2$ and $d\sigma/dx_F$) measured in proton-gold collisions [7]. These results were obtained in the positive $x_F$ region, while our measurement covers the range $-0.25 \leq x_F \leq 0.15$. MC studies based on the Color Octet Model [30] of charmonium production show a symmetric $x_F$ distribution of prompt $J/\psi$ decays. We therefore use the experimental parameterization [7] to extrapolate to the full $x_F$ space. The model dependence of the generated $p_T$ spectrum is of less relevance since our $p_T$ acceptance is essentially flat.

For the $b\bar{b}$ MC simulations, the events generated by PYTHIA are weighted according to a model with various contributions. First, the generated $b$ quark kinematics ($x_F$ and $p_T$) are given by the computation of M. Mangano et al. [31] using the most recent next-to-next-to-leading-logarithm (NNLL) MRST parton distribution functions [32] with a $b$ quark mass of $m_b = 4.75$ GeV/$c^2$ and a QCD renormalization scale $\mu = \sqrt{m_b^2 + p_T^2}$. Second, the intrinsic transverse momenta of the colliding quarks are smeared with a Gaussian distribution leading to $\langle k_T^2 \rangle = 0.5$ GeV$^2$/c$^2$ [33]. Finally, the $b$ fragmentation is described by a Peterson function [34] with a parameter $\epsilon = 0.006$ [5]. The subsequent $b$-hadron production and decay are controlled by the PYTHIA default parameters. The $b$-hadron average lifetime is taken from Ref. [9]: $\tau_b = 1.564 \pm 0.014$ ps.

The sensitivity of the final result on the $b\bar{b}$ cross section within our acceptance ($\Delta\sigma(b\bar{b})$) has been determined by varying the following $b\bar{b}$ MC model parameters: the parton distribution functions (from MRST to CTEQ5 [35]), the $b$ quark mass (in the range $m_b \in [4.5, 5.0]$ GeV/$c^2$), the QCD renormalization
scale (from $0.5\sqrt{m_b^2 + p_T^2}$ to $2\sqrt{m_b^2 + p_T^2}$), the fragmentation function (from the Peterson form [5,36,37] with parameter $\epsilon \in [0.002, 0.008]$, to the Kartvelishvili form [38] with parameter $\alpha_\beta = 13.7 \pm 1.3$ [37]), the intrinsic transverse momentum distribution (with $\langle k_T^2 \rangle$ in the range [0.125,2.0] GeV$^2$/c$^2$) and the fraction of $b$-baryons produced in the $b$ hadronization process in the range [0, 12]%$. The observed variations in the detection efficiencies have been included in the systematic error.

The generated particles are propagated through the geometry and material description of the detector using the Geant 3.21 package [39]. A simulation of the detector response to particles is achieved by reproducing the digitization of electronic signals, with a realistic description of hit efficiencies and problematic channels. The MC events are subjected to a full trigger simulation and reconstructed with the same algorithms as the data.

4 **J/ψ Event Selection**

Since the observed number of prompt $J/\psi$ decays is used as a normalization factor of the $b\bar{b}$ cross section measurement, we begin by selecting and counting the number of $J/\psi$ decays ($N_P$), before applying the detached vertex analysis. The lepton reconstruction in the OTR is seeded with the dilepton trigger track candidates; moreover a matching criteria is applied between the reconstructed track and the trigger track candidate in both the OTR and the VDS. The $J/\psi \rightarrow l^+l^-$ selection and counting procedure differs between the muon and electron channels, due to differences in the background levels, shapes and triggering conditions.

4.1 **J/ψ → μ⁺μ⁻**

Three criteria are used to select $J/\psi \rightarrow \mu^+\mu^-$ decays and to purify the reconstructed sample from non-$J/\psi$ background: a dimuon vertex requirement and muon identification cuts in both the MUON and the RICH systems. The cuts are chosen to give the best signal significance ($S/\sqrt{B}$) on the number of seen $J/\psi$ ($S$) with the observed background ($B$). The resulting spectrum is shown in Fig. 2, with $N_P = 2880 \pm 60$ prompt $J/\psi \rightarrow \mu^+\mu^-$ decays. The like-sign spectrum shown in Fig. 2 is obtained from the same set of triggered events: the small discrepancy in number of reconstructed events in the background regions arises from the difference in trigger acceptance between the two cases and from physics contributions to the unlike-sign spectrum (Drell-Yan, open charm production).
Fig. 2. The $\mu^+\mu^-$ invariant mass spectrum, after the $J/\psi$ selection cuts. The fit (solid line) assumes a Gaussian signal and an exponential background. The like-sign spectrum (dashed line) shows small discrepancies in the background regions (see text); it is not used in the analysis and serves only for illustration purposes.

4.2 $J/\psi \rightarrow e^+e^-$

The selection of $J/\psi \rightarrow e^+e^-$ decays is more complex due to very large background contributions, mainly from pions interacting in the ECAL and hadrons overlapping with energetic neutral showers. Due to such background, a clear $J/\psi$ signal can be reconstructed only by means of strong electron identification requirements. Electron identification in the ECAL is based both on the ratio of the cluster energy $E$ to the momentum $p$ from tracking ($E/p$) and on the search for electron bremsstrahlung signals:

- the $E/p$ distribution is established for a purified $J/\psi \rightarrow e^+e^-$ sample by using a double-bremsstrahlung requirement as described in the following paragraph. The $E/p$ spectrum is compatible with a Gaussian distribution of mean 1.00 and width $\sigma \approx 9\%$;

- bremsstrahlung photons emitted upstream of the magnet maintain the original electron direction; thus they can be used to correct the electron momentum at the vertex and they also provide a clean electron signature (bremsstrahlung tag).

The $e^+e^-$ invariant mass distribution is shown in Fig. 3(a), requiring only that $E/p$ be within $1 \sigma$ from unity for each track. Figs 3(b,c) show the improvements in signal significance that are obtained when the bremsstrahlung selection is added to the $E/p$ requirement.

Table 1 lists the number of prompt $J/\psi$ signal events found for different $E/p$ and bremsstrahlung requirements. Using these $J/\psi$ sets one can measure the
Fig. 3. The $e^+e^−$ invariant mass spectra, with an $E/p$ cut at 1 $σ$ on both $e^+$ and $e^−$ tracks; (a) no bremsstrahlung requirement; (b) with at least 1 identified bremsstrahlung photon; (c) with two identified bremsstrahlung photons. The fits (solid lines) assume a Gaussian signal and a polynomial shape for the background. The background shapes (dashed lines) differ from the dimuon case (Fig. 2), due to $E_T$ and invariant mass cuts in the trigger.

Table 1

| Bremsstrahlung requirement | 0.5σ | 1σ | 2σ | 3σ |
|----------------------------|------|----|----|----|
| None                       | 895 ± 75 | 2553 ± 184 | 5362 ± 292 | [5710 ± 380 ± 280] |

The number of prompt $J/ψ → e^+e^−$ with different bremsstrahlung requirements and different $E/p$ cuts on both tracks. The bremsstrahlung tag probability for a single electron is reported for each $E/p$ cut. The value at 3$σ$ in square brackets is obtained by extrapolation from samples with stronger electron identification cuts (see text).
bremsstrahlung tag probability for a single electron redundantly, resulting in an average $\epsilon_{\text{brems}} = 0.34 \pm 0.02 \text{(stat)} \pm 0.02 \text{(sys)}$. This measured tag probability is in good agreement with expectations from MC simulations. The systematic uncertainties include the observed fluctuations when varying the fitting functions and range used to estimate the amount of $J/\psi$ events in the invariant mass spectra.

The good knowledge of the particle identification efficiencies allows us to infer the number of prompt $J/\psi$ present in a sample where looser identification cuts have been applied and where no clear $J/\psi$ signal is directly visible. Under such conditions, the normalization factor $N_P$ can be obtained while preserving reasonable statistics for the final detached vertex analysis, which relies only on the vertex separation cuts for the background rejection, as will be shown in Sect. 5.

The total number of prompt $J/\psi$ in our sample with no bremsstrahlung tag requirement and with a $3\sigma E/p$ cut is $N_P = 5710 \pm 380 \text{(stat)} \pm 280 \text{(sys)}$ (entry in square brackets in Table 1).

### 5 Detached Vertex Analysis

The long decay length of $b$-hadrons is used to separate the $b \to J/\psi$ events from the prompt $J/\psi$ and to further reduce the non-$J/\psi$ background. The decay length ($\Delta z$), defined as the distance along the beam axis between the $J/\psi$ decay vertex and the closest wire (primary production point), is shown in Fig. 4 for a purified sample of $J/\psi \to e^+e^-$ events (2 bremsstrahlung requirement). The width of the prompt $J/\psi$ vertex distribution is more than 10 standard deviations smaller than the mean decay length of triggered $b$-hadrons ($\approx 0.8$ cm). Given the achieved vertex resolution, a detached vertex cut proves to be efficient in the signal selection. Additionally, a cut on the minimum impact parameter of both leptons to the production vertex ($I_v$) or to the wire ($I_w$) is applied in the detached vertex selection. The minimum impact parameter distribution of prompt $J/\psi \to e^+e^-$ decay leptons (purified sample) to the wire is compared to the corresponding distribution from $b \to J/\psi$ decay leptons (dashed line) in Fig. 5, illustrating the potential gain in $b \to J/\psi$ signal-purity when applying a minimum impact parameter cut.

The prompt $J/\psi$ which survive the detached vertex cuts cannot be distinguished from $b \to J/\psi$ events and their contribution to the detached $b$ signal has to be determined from MC. A study has been performed to ensure that the simulation tool reliably reproduces the real data for the physical quantities defining the detached selection cuts, as illustrated by the good MC-data agreement in Fig. 4 and Fig. 5. In the simulation of the $\mu^+\mu^-$ channel, a Gaussian
Fig. 4. The decay length ($\Delta z$) of purified $J/\psi \rightarrow e^+e^-$ events (2 bremsstrahlung sample, $\approx 15\%$ background) for real data and compared to MC prompt $J/\psi$ events. The resolutions of both data and MC distributions are in agreement ($715 \pm 24 \mu m$ and $721 \pm 10 \mu m$, respectively). The arrows mark the cuts applied in the detached vertex analysis.

Fig. 5. The minimal impact to the wire ($I_w$) of the two lepton tracks for purified $J/\psi \rightarrow e^+e^-$ events (2 bremsstrahlung sample) data and in MC for $J/\psi \rightarrow e^+e^-$ events. The expected shape from $b \rightarrow J/\psi$ decays is shown in dashed line (arbitrary scale). The arrow marks the cut applied in the $e^+e^-$ detached event selection.

distribution has been added to the standard MC track-slopes, increasing the slope errors by 20% in average, in order to match the parameters observed in data and resulting in a similar good MC-data agreement as in the $e^+e^-$ case.

The optimization of the detached vertex cuts is achieved by maximizing the ratio $S/\sqrt{B}$, where $S$ is the number of accepted signal events in the MC $b \rightarrow J/\psi$ sample and $B$ the number of background events in real data, observed in the whole upstream region and downstream in the side bins of the $J/\psi$ invariant mass signal. The systematic errors in the final $\sigma(b\bar{b})$ result take into account the variations in the signal estimated under different sets of cuts found by the optimization procedure.
The upstream (a) and downstream (b) invariant $\mu^+\mu^-$ mass spectrum after detached event selection. The downstream curve shows the result of the unbinned likelihood fit, in which the yields of background and signal contributions and the background slope, as defined in the text, were left as free parameters.

The main background contributions expected in the detached sample are due to combinatorics (bad vertex or track reconstruction) and to double semileptonic $c\bar{c}$ or $b\bar{b}$ events. The combinatorial yield is estimated through the observed events in the region upstream of the primary interaction (unphysical region), while the charm background level is estimated by means of MC simulations, assuming a $c\bar{c}$ production cross section of 40 $\mu$b/nucleon for our 920 GeV proton beam energy [40]. The $b\bar{b}$ background yield is estimated by studying the MC mass spectrum of $b\bar{b}$ events surviving trigger and selection cuts, with a contribution relative to the observed yield of $b \rightarrow J/\psi \rightarrow l^+l^-$ events.

5.1 $b \rightarrow J/\psi \rightarrow \mu^+\mu^-$

The detached vertex cuts found by the optimization procedure in the dimuon channel are: a minimum decay length of 7.5 times the uncertainty on the secondary vertex position $^1$, a minimum track impact parameter to the assigned primary vertex of 160 $\mu$m and a minimum track impact parameter to the assigned wire of 45 $\mu$m.

Only 11 events survive these cuts downstream of the primary interaction region with invariant mass above 2.1 GeV/c$^2$ (see Fig. 6). Only a single event is found upstream of the primary interaction.

In order to use the full information of the detached invariant mass spectrum, an unbinned likelihood fit is performed, using the Gaussian parameters of the prompt $J/\psi$ signal together with an exponential background contribution with $^1$ The typical cutoff is at about 5 mm, with some events down to 3 mm being accepted.
free slope. The output of the fit shown in Fig. 6 yields $1.9^{+2.2}_{-1.5}$ $b \to J/\psi$ events. The background slope obtained from the fit is compatible with the simulated charm and bottom quark background shape, although the statistics are low.

From simulation, the expected background from prompt $J/\psi$ decays is negligible. The estimated background contributions of semileptonic charm and bottom quark decays, together with the single event expected from combinatorial background (seen upstream) and the number of fitted signal events, are compatible with the 11 events observed downstream of the primary interaction region.

To determine $\Delta \sigma(b\bar{b})$ in our $x_F$ range, the prompt $J/\psi$ and $b \to J/\psi$ MC events are submitted to the same analysis chain used for real data. From simulation we obtain the efficiency terms entering in the cross section formula: $\varepsilon_R \cdot \varepsilon_A = 0.41 \pm 0.01$. The corresponding $b\bar{b}$ cross section measured in the $\mu^+\mu^-$ channel is $\Delta \sigma(b\bar{b}) = \sigma_B / A = 16^{+18}_{-12}$ nb/nucleon, obtained by using the weighted average of our target materials. All parameters contributing to the measurement (Eq. 2) are summarized in Table 2.

### 5.2 $b \to J/\psi \to e^+e^-$

The cut optimization procedure in the $e^+e^-$ channel results in the following criteria: a minimum decay length of 0.5 cm, a minimum track impact parameter to the assigned wire of 200 $\mu$m or alternatively an isolation of the lepton candidate at the $z$ of the wire from any other track by a minimum distance of 250 $\mu$m. The types and values of the cuts are not exactly the same as in the muon analysis due to the very different background conditions.

The detached selection yields 8 events upstream of the primary interaction region (pure combinatorial background) and 19 downstream events (see Fig. 7). Among the downstream candidates, 10 events are found in the $J/\psi$ mass window ($2.8 \text{ GeV}/c^2 < m_{e^+e^-} < 3.3 \text{ GeV}/c^2$).

Similarly to the muon analysis, an unbinned likelihood fit is performed on the invariant mass spectrum of the detached downstream $e^+e^-$ candidates. The shape of the signal is taken from simulated $b \to J/\psi$ decays, while the background shape is a combination of the shapes obtained from simulated double semileptonic bottom quark decays and from pure combinatorial (upstream) events. The result of the likelihood fit is shown in Fig. 7(b), yielding $8.6^{+3.9}_{-3.2}$ $b \to J/\psi$ events. When the background shape used in the fit is replaced by a pure combinatorial background shape or by a pure double semileptonic $b\bar{b}$ background, a $\pm 7\%$ variation is observed in the number of $b \to J/\psi$ events. This contribution is included in the systematic error of our measurement.
The expected background from prompt $J/\psi$ decays is of less than 0.2 events at the 90% C.L. in the whole downstream region. As in the $\mu^+\mu^-$ case, the estimated background yields from semileptonic charm and bottom quark decays, together with the expected combinatorial background level (8 events seen upstream) and the fitted signal, are compatible with the 19 events observed downstream of the primary interaction region.

Different cut optimization techniques and assumptions have been tested to verify the stability of the signal. The optimizations are performed simultaneously on the three detached vertex cuts ($\Delta z$, $I_w$ and the isolation cut) using the background from real data and the downstream $b \rightarrow J/\psi \rightarrow e^+e^-$ events from MC. Independently on the optimization criteria, a $J/\psi$ signal with significance greater than 2 $\sigma$ is always observed in the downstream part of the spectrum, while a visible $J/\psi$ signal is never present in the upstream part. In Fig. 8, the selected detached events are displayed in a scatter plot of the invariant mass versus the measured decay length ($\Delta z$): a clustering is observed around the $J/\psi$ invariant mass for large $\Delta z$ values in the region downstream of the primary interaction.

To confirm the $b$ assignment of the selected events, an unbinned maximum likelihood fit is performed on the decay length measurements. A mean decay length of $0.81 \pm 0.03$ cm on $b\bar{b}$ events is expected from MC. We measure $1.0 \pm 0.3$ cm for the 10 downstream events in the $J/\psi$ region ($2.8 \text{ GeV}/c^2 < m_{e^+e^-} < 3.3 \text{ GeV}/c^2$), in good agreement with the $b\bar{b}$ interpretation, while the 8 upstream background events yield a mean decay length of $0.36 \pm 0.13$ cm (measured using $-\Delta z$). To further verify that the selected events have features compatible with $b$ decays, we performed a visual inspection of the candidates studying extra detached vertices (from the other $b$ decay) and extra tracks attached to the $J/\psi$ vertex. Both categories of events are observed, and
Fig. 8. The scatter plot of $e^+e^-$ invariant masses versus the measured decay length ($\Delta z$) for the selected detached events. The shaded region is removed by the $\Delta z$ cut. The horizontal line shows the mean $J/\psi$ invariant mass value. A clear clustering of events around the $J/\psi$ mass with large $\Delta z$ is observed in the downstream sample.

their yields are compatible with MC expectations. Within the limits of the available statistics, the $J/\psi$ $x_F$ and $p_T$ distributions are also compatible with the $b \rightarrow J/\psi$ interpretation.

From MC simulation, we obtain the efficiency terms entering in the cross section measurement (Eq. 2): $\varepsilon_R \cdot \varepsilon_{\Delta z} = 0.44 \pm 0.02$. The corresponding $b\bar{b}$ cross section measured in the $e^+e^-$ channel is $\Delta \sigma(b\bar{b}) = \sigma_{A\bar{A}}/A = 38^{+18}_{-15}$ nb/nucleon, obtained by using the weighted average of our target materials. All the parameters used in Eq. 2 are summarized in Table 2.

6 Combined Cross Section Measurement

The two measurements, $\Delta \sigma(b\bar{b}) = 16^{+18}_{-12}$ nb/nucleon and $\Delta \sigma(b\bar{b}) = 38^{+18}_{-15}$ nb/nucleon, obtained in the muon and electron channels, respectively, are compatible within statistical uncertainties. In order to extract the maximum information on the $b\bar{b}$ production cross section from our data, we combine the $\mu^+\mu^-$ and $e^+e^-$ likelihoods in a four parameter likelihood maximization ($\Delta \sigma(b\bar{b})$, $\mu^+\mu^-$ background slope, $\mu^+\mu^-$ and $e^+e^-$ background yields) on the detached candidates. The fit provides our final result of the $b\bar{b}$ production cross section:

$$\Delta \sigma(b\bar{b}) = 30^{+13}_{-11}(\text{stat}) \text{ nb/nucleon},$$

where the quoted uncertainty has been estimated directly from the fit (see Fig. 9).

![Graph](image_url)

Fig. 9. The likelihood fits for the $b\bar{b}$ production cross section in our $x_F$ range ($\Delta\sigma(b\bar{b})$) using the $\mu^+\mu^-$ and $e^+e^-$ events separately (dotted and dashed line respectively) and in a combined analysis (solid line).

The main sources of systematic uncertainty in the present measurement, which are not related to the final $b\bar{b}$ statistics, are due to the prompt $J/\psi$ cross section reference (11%), the branching ratio $\text{Br}(b\bar{b} \rightarrow J/\psi X)$ (9%), the trigger and detector simulation (5%), the prompt $J/\psi$ MC production models (2.5%),
Fig. 10. The comparison of the HERA-B (2000) $\sigma(b\bar{b})$ value with other experiments and with the theoretical predictions of R. Bonciani et al. [2] updated with the NNLL parton distribution function in [32] (solid line: central value, dashed lines: upper and lower bounds) and N. Kidonakis et al. [3] (dot-dashed line: central value, dotted lines: upper and lower bounds).

the $b\bar{b}$ MC production models (5%), the prompt $J/\psi \rightarrow e^+e^-$ counting (5%) and the carbon-titanium difference in efficiencies (1.7%). Other contributions are below the 1% level. Uncertainties stemming from the background shapes used in the maximum likelihood fits on the invariant masses and from the cut values are dominated by the low statistics of observed detached events. For these sources we assign conservative uncertainties of $^{+10}_{-24}$% and 13% to the $\mu^+\mu^-$ and $e^+e^-$ channels, respectively. The overall systematic uncertainty for our measurement, averaged over the muon and electron channels, is of $^{+20}_{-23}$%.

To compare our measurement with theoretical predictions, we extrapolate the $\Delta\sigma(b\bar{b})$ measurement to the full $x_F$ range, relying on the $b\bar{b}$ production and decay model described in Sect. 3 which foresee that 92% of $J/\psi$ from $b$ decays are produced in our $x_F$ range. We obtain the total $b\bar{b}$ production cross section:

$$\sigma(b\bar{b}) = 32^{+14}_{-12}(\text{stat})^{+6}_{-7}(\text{sys}) \text{ nb/nucleon.}$$ (4)

In Fig. 10, this result is compared with the latest QCD calculations [2,3] beyond next-to-leading order (NLO). The two predicted values at 920 GeV proton beam are, respectively, $\sigma(b\bar{b}) = 25^{+20}_{-13} \text{ nb/nucleon}$ \cite{2} and $\sigma(b\bar{b}) = 30 \pm 13 \text{ nb/nucleon}$, in good agreement with our measurement. In the same figure, the E789 [5] and E771 [6] experimental results obtained with 800 GeV proton interactions on Au and Si, respectively, are plotted and are seen to be compatible (Fig. 10).

\footnote{Value based on Ref. [2], updated with the parton distribution function in Ref. [32].}
7 Conclusions

Events coming from $b \to J/\psi \to l^+l^-$ decays have been identified in a sample of $\approx 1.35$ million dilepton triggered events, acquired in a short physics run during the HERA-B commissioning period in summer 2000. The data analysis results in the identification of $1.9^{+2.2}_{-1.5}$ $b \to J/\psi \to \mu^+\mu^-$ candidates and $8.6^{+3.9}_{-3.2}$ $b \to J/\psi \to e^+e^-$ candidates.

From these candidates, we compute the $b\bar{b}$ production cross section by normalizing to the known prompt $J/\psi$ cross section. In the $J/\psi$ kinematic range $-0.25 < x_F < 0.15$, we obtain $\Delta \sigma(b\bar{b}) = 16^{+18}_{-12}$ nb/nucleon and $\Delta \sigma(b\bar{b}) = 38^{+18}_{-15}$ nb/nucleon in the muon and electron channels, respectively. Within statistical errors, the two results are compatible. The combined result of the $b\bar{b}$ production cross section measured by HERA-B at 920 GeV using $pC$ and $pTi$ interactions in our $x_F$ range is $\Delta \sigma(b\bar{b}) = 30^{+13}_{-11}$ (stat) $\pm 6$ (sys) nb/nucleon. Extrapolating this measurement to the full $x_F$ range, we obtain the total $b\bar{b}$ production cross section:

$$\sigma(b\bar{b}) = 32^{+14}_{-12}(\text{stat})^{+6}_{-7}(\text{sys}) \text{ nb/nucleon}. \quad (5)$$

This result is compatible with the existing measurements [5,6] and in agreement with the most recent QCD predictions [2,3] beyond NLO.

Acknowledgments

We express our gratitude to the DESY laboratory and to the DESY accelerator group for their strong support since the conception of the HERA-B experiment. The HERA-B experiment would not have been possible without the enormous effort and commitment of our technical and administrative staff. It is not possible to list here the many individuals who have contributed to HERA-B. We are especially grateful to the following persons and their groups: G. Avoni, C. Baldanza, J. Bizzell, A. Cotta-Ramusino, F. Czempik, I. D’Antone, J. Davila, J. Dicke, A. Donat, U. Dretzler, A. Epifantsev, S. Fricke, W. Funk, A. Gutierrez, F. Hansen, M. Harris, S. Hennenberger, J. Hogenbirk, M. Jablonski, V. Kiva, M. Kolander, Y. Kolotaev, L. Laptin, H. Leich, H. Lüdecke, Q. Li, K. Y. Liu, P. Liu, C. Lu, K. Ludwig, J. McGill, E. Michel, N. Murthy, E. Novikov, S. Omelchuk, D. Padrazo, H. B.
