Running title: Addison disease

Word count: 2292 (text), 250 (abstract)
ABSTRACT

**Design:** Addison disease (AD) is a rare autoimmune disease (AID) of the adrenal cortex, presenting as an isolated AD or part of autoimmune polyendocrine syndromes (APSs) 1 and 2. Although AD patients present with a number of AID co-morbidities, population-based family studies are scarce. We aimed to carry out an unbiased study on AD and related AIDs.

**Methods:** We collected data on patients diagnosed with AIDs in Swedish hospitals, and calculated standardized incidence ratios (SIRs) in families for concordant AD and for other AIDs, the latter as discordant relative risks.

**Results:** The number of AD patients was 2,852, which accounted for 0.4% of all hospitalized AIDs. A total of 62 persons (3.6%) were diagnosed with familial AD. The SIR for siblings was remarkably high, reaching 909 for singleton siblings diagnosed before age 10 years. It was 32 in those diagnosed past age 29 years and the risk for twins was 323. SIR was 9.44 for offspring of affected parents. AD was associated with 11 other AIDs, including thyroid AIDs and type 1 diabetes, and some rarer AIDs such as Guillain-Barre syndrome, myasthenia gravis, polymyalgia rheumatica and Sjögren syndrome.

**Conclusions:** The familial risk for AD was very high implicating genetic etiology, which for juvenile siblings may be ascribed to APS-1. The adult part of sibling risk was probably contributed to by recessive polygenic inheritance. AD was associated with many common AIDs; some of these were known co-morbidities in AD patients while some other appeared to more specific for a familial setting.
Addison disease (AD) is an autoimmune disease (AID) characterized by a gradual autoantibody destruction of the adrenal cortex with resulting impaired production of corticosteroids and mineralocorticoids (1). Most patients express autoantibodies against 21-hydroxylase, an enzyme in the steroid synthetic pathway. The global prevalence is estimated at 14/100,000, where 63% are women (2). The reported prevalence in Norway is also 14/100,000 (3). All symptomatic patients need medical attention and the standard treatment is hormone replacement therapy, which allows most patients to remain in good health (1). AD is a common component in autoimmune polyendocrine syndrome (APS) in which multiple endocrine glands are attacked by autoantibodies (4, 5). AD is part of the rare juvenile APS-1, which is usually diagnosed before age 15 years and is caused by recessive mutations in the autoimmune regulatory gene (AIRE) (4, 5). The more common adult-onset APS-2 is defined through morbidty of at least two of the following three AIDs: AD, type 1 diabetes or autoimmune thyroid disease, but it may also include other AIDs (4). AD patients may present with multiple AIDs, irrespective of APS-2; among Norwegian and Swedish patients only less than 40% were diagnosed with isolated AD (1, 3). In these studies, the most common AID comorbidities were thyroid AID (in half of the patients) and type 1 diabetes (in over 10% of the patients). A family history of AD was reported in 10% of the Norwegian patients and 6% of the Swedish ones (1, 3). A small case-control study from Poland reported that 3% of the family members were also diagnosed with AD and that thyroid AID was found in almost 30% of the family members (6). In our previous family studies, AD was associated with type 1 diabetes and Graves disease in family members (7, 8). AD was found to be in excess after diagnosis of asthma and subsequent type 2 diabetes was increased after a diagnosis of AD (9, 10).

AD (and APS-2) is a polygenic condition for which no single ‘major’ gene has been identified, in spite of the high twin heritability (11-13). Twin studies have shown a high co-aggregation of AD with other AIDs, such as Hashimoto thyroiditis, Graves disease, celiac disease and type 1 diabetes (12, 13). The human leukocyte antigen (HLA) locus was for a long time the only significant genetic risk factor for AD, as it was for many other AIDs; the HLA DQ/DR regions regulate the antigen presentation to the T-cell receptor (5, 14). It was recently shown that amino acid polymorphisms within HLA class II exon 2 mediate the APS risk and differentiate between thyroid and polyglandular autoimmunity (15). Association and sequencing studies have identified several low-risk genes which are also shared between some other AIDs (11). These include AIRE, BACH2, TTPN22, CTLA4, CLEC6A and HLA-DRB1, which jointly may account for 20% of the heritability of AD (11, 16). These genes are relevant in many immune functions. For example, in addition to the HLA locus, AIRE encodes a protein which regulates the expression of autoantigens and negatively selects autoreactive T-cells in the thymus (4, 5). BACH2 maintains regulatory T-cell function and B-cell maturation, and CTLA-4 (cytotoxic T-lymphocyte associated protein 4) acts as a major negative regulator of T-cell responses (4, 5). These pathways have been highlighted by the ever increasing use of immune checkpoint inhibitors in cancer therapy. The applied monoclonal antibodies target checkpoint receptors, such as CTLA-4, and autoimmune side-effects are common (17, 18). In fact, some authors have suggested that the side-effects of immune checkpoint inhibitors would constitute a new type of APS (19).

Due to the sparsity of population-based family studies in AD, we used Swedish hospital data to characterize familial clustering of concordant (between AD) and discordant (AD and other AIDs). Concordant risks were assessed separately for offspring of affected parents and for siblings in order to draw conclusions about the mode of association. The discordant analysis was conducted bidirectionally: first, the relative risk was calculated for any other AID in families of AD, followed by the relative risk for AD in families with other AIDs.

METHODS

AID patients were identified from the Swedish Hospital Discharge Register (years 1964 through 2012, full national coverage from 1986 onwards) and the Outpatient Register (2001 through 2012). Only the first AID diagnosis was included. Of a total of 769,991 patients with any of in total 43
AIDs, 51% were identified from the Inpatient Register and 49% were identified from the Outpatient Register. The International Classification of Diseases (ICD) codes were used for identification of AIDs as described elsewhere (20). Family relationships were obtained from the Multigeneration Register, containing the Swedish population in families and covering parental generations for a century (21). As family members, only first-degree relatives of offspring-parent pairs and siblings were considered; ‘the offspring generation’ was born after 1931 and siblings could be defined only in this generation; ‘the parental generation’ was born any time earlier. By the year 2012, the offspring generation reached age 80 years. For the parental generation there was no age limit. Information from the registers was linked at the individual level via the national 10-digit civic registration number. In the linked dataset, civic registration numbers were replaced with serial numbers to ensure the integrity of all individuals. Spouses were identified through the first common child.

Standardized incidence ratios (SIRs) were calculated for the offspring generation as the ratio of observed to expected number of cases. The expected numbers were calculated for all individuals without a first-degree family history of a specific AID, and the rates were standardized by 5-year-age, gender, period (5 year groups), socioeconomic status and residential area. The 95% confidence interval (95%CI) of the SIRs were calculated assuming a Poisson distribution. Separate SIRs were calculated for offspring when only parents or only singleton siblings/twins were probands, i.e., they were diagnosed with concordant AID. In the analysis of discordant AIDs, bidirectional (i.e., AD-AIDx and AIDx-AD) associations were considered. Results are shown for discordant associations if any of the comparisons were significant (95% CI did not include 1.00).

RESULTS

The number of AD patients in the offspring generation (to whom risks were calculated) was 1,735 with a mean diagnostic age (i.e., first hospital contact) of 39.7 years; considering also their parents the total number was 2,852 of whom 46.5% were males (Table 1). The total AID population amounted to 519,180 patients in the offspring generation of 8.5 million. Thus, AD accounted for 0.3% of all AIDs in the offspring generation, and 0.4% in the whole population.

Concordant familial risks

A total of 62 persons were diagnosed with familial AD in the offspring generation, 8 with a parental and 54 with a sibling history (4 of the affected parental probands had remarried and were not included among the 58 individuals for ‘All’). Among the total of 1735 AD patients, 3.6% were familial. Familial risks for AD are shown in Table 2 for offspring whose first-degree relatives (parents or siblings as probands in the top and only parents as probands in the bottom) were diagnosed with concordant disease. The overall familial risk for AD risk was 41.49 and almost identical for women and men. The risk depended on the age at diagnosis, being highest (245.54) for 0-9 year olds and lowest (24.79) for those older than 29 years. The SIR was 9.44 for offspring whose parents were affected and was significant for offspring diagnosed at age 10-29 years. Of note, only 8 patients had an affected parent while 54 siblings shared the disease. We also planned to analyze the risk between spouses but no concordant couples were identified.

Risks for siblings are shown in Table 3, separating singleton siblings and twins. For singleton siblings, the SIR was 909.09 when diagnosed below age 10, and declining to 32.03 at age over 29 years. For twins, the SIR was 323.62, the diagnostic age range was 27-67 years. All twin pairs were of the same sex.

Discordant familial risks

We analyzed familial risks for discordant AIDs and the results are shown in Table 4 when any of the bidirectional analyses were significant; this was found for 11 other AIDs (both sexes). Both of the bidirectional SIRs were significant for 8 AIDs, including common AIDs and rarer ones, such as
polymyalgia rheumatica and Sjögren syndrome. Only one directional increases were noted for AD in families of rheumatoid arthritis patients, and only for Guillain-Barre syndrome and myasthenia gravis in families of AD patients. The highest risk for AD (3.44) was noted in families of type 1 diabetes. The highest risk for discordant AID in AD families was for myasthenia gravis (3.85). Of note, 43 AD patients were found in polymyalgia rheumatica families, ranking third after families with rheumatoid arthritis (79) and Graves disease (47). None of the sex-specific SIRs differed between men and women (i.e., the 95%CIIs overlapped). Nevertheless, only female bidirectional SIRs were increased for celiac disease and Sjögren syndrome. Three sex-specific bidirectional SIRs were significantly increased in both sexes in associations of AD with type 1 diabetes, Graves disease and Hashimoto thyroiditis. Discordant associations are summarized in Fig. 1 for sexes combined.

DISCUSSION

The present nation-wide study covered a rare AID, which accounted for 0.4% of all hospitalized AIDs in Sweden. Familial AD accounted for 3.6% among all AD patients. We provided novel population-based familial risk estimates, which were very high, 41.49, and equal for men and women. Such high familial risk could be anticipated from the twin-based heritability estimates (12, 13). Yet they were far higher than our previous results on other AIDs. For example, concordant risk for offspring with Graves disease with an affected parent was 4.49 (8). A surprising finding was that most familial cases (54/62) were siblings rather than offspring of affected parents. The sibling risk was remarkably high, reaching 909 for the youngest singleton siblings but remaining as high as 32 in those diagnosed past age 29 years. The risk for twins was 323, and all but one twin were diagnosed past age 29 years. Even though all concordant twins were of the same sex, it is likely that many of them were dizygotic as reported from the Swedish Twin Register (13). In our previous studies, the concordant risk for young siblings diagnosed with type 1 diabetes was 12.3, and 8.33 for siblings diagnosed with Graves disease at any age (7, 8). The SIRs for twins were somewhat over 20 for type 1 diabetes and 16.6 for Graves disease.

It is likely that the early onset AD population consisted of APS-1, usually diagnosed before 15 years of age (4, 22). The syndrome is caused by recessive AIRE mutations, which is consistent with the extremely high risk between young siblings. No twins were identified at ages below 27 years, which implies that they were not APS-1 patients. The risk for singleton siblings diagnosed at age >29 years was 32.03 while the risk for offspring of affected parents was 9.44. The case numbers were small but the difference was significant. The common reasons for the difference in risks between siblings and offspring of affected parents are either childhood environmental sharing or recessive inheritance. In view of lacking information on strong environmental risk factors and the finding that no spouses shared an AD diagnosis, inherited factors are likely to contribute to the observed sibling risks.

Family studies on AD are rare and include the recent small hospital-based study from Poland and twin studies from Sweden, discussed in Introduction (6, 11, 12). However earlier studies on other AIDs have observed significant associations with AD in family members, including studies on vitiligo, thyroid diseases and multiple sclerosis (23-25). In the present study we showed significant familial associations for AD with 11 other AIDs, including the ones that are the most common co-morbidities in individual patients: thyroid AIDs and type 1 diabetes, and some rarer ones such as celiac disease. We had no data on some other relatively common co-morbidities, such as vitiligo or gonadal failure (1, 3). Pernicious anemia has been found to be a co-morbidity in Swedish patients but we found no increase in familial risk (1). Rheumatoid AIDs were clearly underrepresented among the associated AIDs, with the exception of polymyalgia rheumatic, systemic lupus erythematosus and Sjögren syndrome. Rheumatoid arthritis is the most common AID in Swedish hospital records, and it showed a modest association (1.27) and of borderline significance only in AD families (26). Novel associations with high SIRs were found for Guillain-Barre syndrome, myasthenia gravis, polymyalgia rheumatica and Sjögren syndrome. The genetic link between AD and myasthenia gravis and polymyalgia rheumatica may be the HLA locus (27, 28). Co-morbidity of AD and myasthenia gravis has previously been reported (29).
Limitations of the present study include the low patient numbers because of the rarity of AD, and many comparisons, whereby some of the results may yield chance findings. The design of applying bidirectional analysis will in part alleviate the problem of multiple comparisons, as parent-offspring pairs are independent in the bidirectional analysis. Thus significant results in the bidirectional analyses, as was the case for most observed associations, provide support for “true” associations. The strengths of the study were diagnostics in a standard way in a high-level health care system, accessible to the population at large without economic barriers. The family relationships were obtained from the Swedish Multigeneration Register with unbiased and complete family relationships (21).

In summary, we found a very high familial risk for AD, particularly among siblings. The juvenile component of the risk could be ascribed to ASP-1. The adult component of sibling risk was probably contributed to by polygenic inheritance. AD was associated with many common AIDs, some of which were known co-morbidities in AD patients. Significant familial associations were also found for rare AIDs, such as Guillain-Barre syndrome, myasthenia gravis, polymyalgia rheumatica and Sjögren syndrome.

FUNDING
The study was supported by the European Union’s Horizon 2020 research and innovation program, grant No 856620.
