The Nonlocal Pancharatnam Phase in Two-Photon Interferometry

Poonam Mehta, Joseph Samuel and Supurna Sinha

(Dated: September 6, 2010)

We propose a polarised intensity interferometry experiment, which measures the nonlocal Pancharatnam phase acquired by a pair of Hanbury Brown-Twiss photons. The setup involves two polarised thermal sources illuminating two polarised detectors. Varying the relative polarisation angle of the detectors introduces a two photon geometric phase. Local measurements at either detector do not reveal the effects of the phase, which is an optical analog of the multiparticle Aharonov-Bohm effect. The geometric phase sheds light on the three slit experiment and suggests ways of tuning entanglement.

PACS numbers: 03.65.Vf, 25.75.Gz, 95.75.Kk 42.50.-p

Introduction :- The familiar two slit experiment in quantum mechanics describes the interference of a single particle with itself. However, there are also quantum processes that describe the interference of a pair of particles with itself. As shown by Hanbury Brown and Twiss (HB-T) [1] about fifty years ago, such interference is observed in the coincidence counts of photons. Their original motivation was to measure the diameters of stars replacing Michelson interferometry by intensity interferometry. Their work was initially met with scepticism because the quantum mechanical interpretation of the proposed experiment was unclear at the time. The resulting controversy led to the birth of the new field of quantum optics. Intensity interferometry is now routinely used in a variety of fields, from nuclear physics [2] to condensed matter [3].

In the nineteen eighties, Berry discovered [4] the geometric phase in quantum mechanics, which has now been applied and studied in various contexts [5]. It was soon realised that Berry’s discovery had been anticipated by Pancharatnam’s work [6] on the interference of polarised light. Pancharatnam’s work is now widely recognised as an early precursor of the geometric phase [7], with a perspective that is far more general [8] than the context in which it was discovered by Berry.

Büttiker [9] noted in the context of electronic charge transport that two-particle correlations can be sensitive to a magnetic flux even if the single particle observables are flux insensitive. The effect of the flux is visible only in current cross correlations and is a genuinely nonlocal and multiparticle Aharonov-Bohm effect [10]. This effect has been experimentally seen in intensity interferometry experiments carried out using edge currents in quantum Hall systems [8] and the theory was further developed in [11, 12] and the possibility of controlled orbital entanglement and the connection to Bell inequalities mentioned.

In this paper, we propose a new experiment with polarised light, which shows geometric phase effects only in the intensity correlations \( G^2 \) and not in the lower order correlations \( G^1 \). The two photon Pancharatnam phase effect is also nonlocal in the precise sense that it cannot be seen by local measurements at either detector. Coincidence detection of photons in two detectors yields counts which are modulated by a phase which has a geometric component as well as the expected dynamical (or propagation) phase. Unlike in earlier studies [13, 14], the effects of the geometric phase are seen only in the cross correlation counts of two detectors. Neither the count rate nor self correlation of the individual detectors shows any such geometric phase effects. The phase is given by half the solid angle enclosed on the Poincaré sphere by the total circuit of a pair of HB-T photons and as expected, is achromatic.

The experimental setup is described below and then a theoretical analysis is given. Finally we conclude with a discussion and a comparison with previous work.

Proposed Experiment :- The experiment consists of having two thermal sources \( S_1 \) and \( S_2 \) illuminate two detectors \( D_3 \) and \( D_4 \) (Fig. 1). This setup is very similar to the HB-T experiment [1]. The only difference is in the use of analysers (shown in red online), which select a particular state of polarisation. The source \( S_1 \) is covered by an analyser \( P_R \), which only permits Right Hand Circular light to pass through it, while the source \( S_2 \) is covered by an analyser \( P_L \), which only permits Left Hand Circular light to pass through. The light is incident on detectors \( D_3 \) and \( D_4 \) after passing through polaroids \( P_3 \) and \( P_4 \) respectively that only permit linearly polarised light to pass through (linear analysers). The angle \( \varphi_{34} \) between the axes of \( P_3 \) and \( P_4 \) and the detector separation \( d_D \) can be continuously varied in the experiment. The measured quantity is the coincidence count \( C \) of photons received at detectors \( D_3 \) and \( D_4 \),

\[
C = G^2 = \frac{\langle N_3 N_4 \rangle}{\langle N_3 \rangle \langle N_4 \rangle}, \tag{1}
\]

where \( N_3 \) and \( N_4 \) are the photon numbers detected at \( D_3 \) and \( D_4 \) per unit time (per unit bandwidth).

As in the HB-T interferometer, we would expect the coincidence counts to vary with the propagation phases and so the counts would depend on the detector separation \( d_D \) and the wavelength \( \lambda \) of the light. The new effect

\[
G = \frac{\langle N_3 N_4 \rangle}{\langle N_3 \rangle \langle N_4 \rangle} = 1 + G^1 \cos \left( \phi_{34} - \phi_{\text{propagation}} \right), \tag{2}
\]
that is present in the polarised version is that we expect the coincidence counts to also depend on \( \varphi_{34} \) and to be modulated by a geometric phase of half the solid angle on the Poincaré sphere shown in Fig. 2.

The geometric phase is achromatic, unlike the propagation phases mentioned above. Note that the path traversed on the Poincaré sphere is not traced by a single photon, but by a pair of HBT photons. Thus the experiment explores a new avatar of the geometric phase in the context of intensity interferometry.

Theory - We now calculate the expected coincidence counts for the detectors \( D_3 \) and \( D_4 \) and show that these counts depend on the geometric phase. For ease of calculation we suppose that we are dealing with a single frequency i.e. a quasi-monochromatic beam. In fact the detectors will have a finite acceptance bandwidth, which has to be incorporated in a more realistic calculation. The principle of the effect comes across better in the present idealised situation.

We write \( a_1^\alpha \) and \( a_2^\beta \) for the destruction operators of the photon modes at the sources \( S_1 \) and \( S_2 \) where \( \alpha \) runs over the two polarisation states. The modes just after the analysers \( P_R \) and \( P_L \) are represented by projections \( a_R^\alpha = P_R^\alpha a_1^\alpha \) and \( a_L^\beta = P_L^\beta a_2^\beta \) where a sum over repeated Greek indices is understood and the projection matrices \( P_R \) and \( P_L \) onto the right and left circular states represent the action of the analysers. The modes at the detectors are characterised by the destruction operators \( a_3^\delta \) and \( a_4^\gamma \). We suppose that the separation \( l \) between the sources and the detectors is much larger than the separation \( d_S \) between the sources and the separation \( d_D \) between the detectors i.e., \( l >> d_S, d_D \).

When light is emitted by a source and received by a detector, it suffers propagation phases and decrease of its amplitude inversely with distance. These effects are captured in the functions \( u_{ij} = \frac{1}{\sqrt{2}} \exp \{ ik(\vec{r}_i - \vec{r}_j) - \omega t \} \), where \( \omega \) is the frequency of the light, \( k \) is the wave vector and \( \vec{r}_i \) and \( \vec{r}_j \) the locations of the detector and source.

With this notation, we express \( a_b^\alpha \) (where \( b = 3,4 \)) as \( a_b^\alpha = P_b^\beta [P_L^\gamma a_2^\beta u_{b2} + P_R^\gamma a_1^\alpha u_{b1}] \) and its Hermitean conjugate \( a_b^{\dagger \alpha} \) as \( a_b^{\dagger \alpha} = [\bar{u}_{b2} a_2^{\dagger \alpha} P_L^{\gamma \beta} + \bar{u}_{b1} a_1^{\dagger \alpha} P_R^{\gamma \beta}] P_b^\beta \) where the overbar stands for complex conjugation and we use the fact that the \( 2 \times 2 \) Hermitean projection matrices \( P \) satisfy \( P^2 = P \) and \( P^{\dagger \gamma} = P^{\dagger \alpha} \).

The quantities of interest [17] are (\( N_3 \), \( N_4 \)) being the photon counts per unit time (per unit bandwidth) at the two detectors \( (D_3 , D_4) \) and (\( N_3 N_4 \)), the coincidence counts, where the :: stands for normal ordering which has to be applied to the number operator product in the numerator of Eq. (1). \( N_b \) is given by \( N_b = a_{\beta}^{\dagger \alpha} a_b^\alpha = \bar{u}_{b2} a_2^{\dagger \alpha} (P_L P_b)^{\gamma \beta} + \bar{u}_{b1} a_1^{\dagger \alpha} (P_R P_b)^{\gamma \beta} \) [\( P_L^{\gamma \beta} a_2^{\dagger \alpha} u_{b2} + P_R^{\gamma \beta} a_1^{\dagger \alpha} u_{b1} \)]. We find

\[
(N_b) = \bar{u}_{b1} u_{b2} (P_R P_b P_R)^{\alpha \beta} (a_1^{\dagger \alpha} a_1^\beta) \\
+ \bar{u}_{b2} u_{b1} (P_L P_b P_L)^{\gamma \beta} (a_2^{\dagger \alpha} a_2^\beta). \tag{2}
\]

From the thermal nature of the sources, \( \langle a_1^{\dagger \alpha} a_1^\beta \rangle = \langle a_2^{\dagger \alpha} a_2^\beta \rangle = \delta^{\alpha \beta} n_B \) where \( n_B \) is the Bose function \( (\exp(\beta \hbar \omega) - 1)^{-1} \) and \( \beta \) the inverse temperature. And we arrive at (\( N_3 \) = \( N_4 \) = \( n_B / 2 \). The computation of (\( N_3 N_4 \)) is slightly more involved but straightforward. The product \( N_3 N_4 \) is a product of four brackets each of which has two terms. When the four brackets are expanded, there are sixteen terms, of which ten vanish. The six nonzero terms combine to give

\[
\langle N_3 N_4 \rangle = n_B^2 \left[ \frac{3}{2} l^2 + \bar{u}_{32} u_{31} \bar{u}_{41} u_{42} \text{Tr} [P_L P_3 P_R P_4 P_L] + \bar{u}_{31} u_{32} \bar{u}_{42} u_{41} \text{Tr} [P_R P_3 P_L P_4 P_R] \right]. \tag{3}
\]
Only the second and third terms in Eq. (3) contain the propagation and geometric phases. The sequence of projections can be viewed as a series of closed loop quantum collapses \( \mathcal{R} \) given by \( \langle R | 3 \rangle \langle 3 | L \rangle \langle L | 4 \rangle \langle 4 | R \rangle 
 \]

\[
\text{Tr} \left[ P_R P_3 P_L P_R P_R \right] = \frac{1}{4} \exp \left( \frac{\Omega}{2} \right),
\]

where \( \Omega \) is the solid angle subtended by the geodesic path \(| R \rangle \rightarrow | 3 \rangle \rightarrow | L \rangle \rightarrow | 4 \rangle \rightarrow | R \rangle\) at the center of the Poincaré sphere. Apart from the phase, the projections also result in an amplitude factor of 1/4 since projections are non-unitary operations leading to a loss in intensity. The final theoretical expression for \( \mathcal{C} \) in the limit \( l \gg d_S, d_D \) is

\[
\mathcal{C} = 3 \left( \frac{1}{2} + \frac{1}{2} \cos \left( \tilde{k}_D \cdot (\tilde{k}_2 - \tilde{k}_1) + \frac{\Omega}{2} \right) \right),
\]

where \( \tilde{k}_i = k_i r_i \) is the wavevector of light seen in the \( i \)th detector. (The propagation phases in Eq. (4) can also be written in an equivalent form with the sources and detectors exchanged.) It is also easily seen that the self correlation \( \langle N_3 N_3 : \rangle \) \( \langle N_1 N_4 : \rangle \) can be obtained by replacing 4 by 3 (3 by 4) in Eq. (3) above. In this case, the sequence of projections \( \text{Tr} \left[ P_R P_3 P_L P_3 P_R \right] \) \( \text{Tr} \left[ P_R P_3 P_L P_3 P_R \right] \) subdents a zero solid angle and the geometric contribution to the phase vanishes. Thus neither the photon counts \( \langle N_3 \rangle, \langle N_4 \rangle \) in individual detectors nor the self correlations \( \langle N_3 N_3 : \rangle, \langle N_4 N_4 : \rangle \) reveal the geometric phase. This supports our claim that the effect described here is only present in the cross correlations and not in the self correlations.

\( \mathcal{C} \) depends on the experimentally tunable parameters \( d_D \) and \( \varphi_{34} \). The geometric part is achromatic and depends only on \( \varphi_{34} \). The propagation part in the phase carries the dependence on \( d_D \) as well as on the wavelength. By changing the angle \( \varphi_{34} \) between the axes of the two polaroids, we can conveniently modulate the geometric component \( \Omega \). If the propagation and geometric phases are set to zero, we find that the correlation \( \mathcal{C} \) takes the value 2, just as in original HB-T interferometry.

**Conclusion:** We have proposed a simple generalisation of the HB-T experiment which uses the vector nature of light to produce a geometric phase. The only difference between the proposed experiment and the HB-T experiment is the presence of polarisers at the sources and detectors. These polarisers cause a geometric phase to appear in the coincidence counts of two detectors which receive linearly polarised light. Neither the count rates nor the self correlations of individual detectors show any geometric phase effects. These appear solely in the cross correlations in the count rates of the detectors. The appearance of the geometric phase cannot be attributed or localised to any single segment joining a source \(( S_1, S_2)\) to a detector \(( D_3, D_4)\). It appears only when one considers the two photon path (Fig. 2) on the Poincaré sphere in its entirety. Our experiment brings out a new result of a conceptual nature, which may not have been guessed without our present understanding of the Pancharatnam phase. The experiment proposed here would be a good demonstration of a purely multiparticle and nonlocal geometric phase in optics. We hope to interest experimentalists in this endeavour. Apart from verifying the theoretical expectation, our proposed experiment suggests further lines of thought concerning multiparticle and nonlocal effects which may be stimulating to research in this area. We mention two of these, the first an application of our ideas to generating controlled entanglement and the second of a more conceptual nature regarding the role of probabilities in quantum mechanics.

**Controlled Entanglement:** The experimental setup described above can be used to make a source of photon pairs with a controlled degree of entanglement. Like many other elementary particles, the photon has spin (polarisation) as well as orbital (spacetime) degrees of freedom. Our idea is to use the polarisation degree of freedom to control the orbital entanglement of photons. Let us replace the two thermal sources of Fig. 4 by a single two-photon source producing a pair of oppositely circularly polarised photons. Each photon is then passed through an interferometer delay line which consists of a short and a long arm with time delays \( t_S \) and \( t_L \). The relative amplitudes and phases of the two paths can be chosen to generate any state in the two dimensional Hilbert space spanned by \( | S \rangle \) and \( | L \rangle \). By such means we can arrange for the incident state at \( P_R \) to be in a spin state of right circular polarisation and in an orbital state \( | \phi \rangle_1 = \alpha | S \rangle_1 + \beta | L \rangle_1 \) and similarly, the incident state at \( P_L \) to be in a spin state of left circular polarisation and in an orbital state \( | \psi \rangle_2 = \alpha' | S \rangle_2 + \beta' | L \rangle_2 \), where \( \alpha, \beta, \alpha', \beta' \) etc are complex numbers. The input state is therefore a direct product of states at \( P_R \) and \( P_L \): \( | \phi \rangle_1 \otimes | \psi \rangle_2 \). By combining the amplitudes for the two photons to arrive at the detectors via the paths 1 – 3, 2 – 4 and 1 – 4, 2 – 3 (direct and exchange) we find that the state at the output is of the form \( | \phi \rangle_3 \otimes | \psi \rangle_4 + \exp(i\Omega/2) | \psi \rangle_3 \otimes | \phi \rangle_4 \), where the geometric phase factor \( \exp(i\Omega/2) \) is the relative phase between the direct and exchange processes. This final two photon state is entangled as it cannot in general be written as a direct product \( | \Psi \rangle_3 \otimes | \Phi \rangle_4 \) of photon states at 3 and 4. The entanglement is generated by particle exchange effects rather than interactions. The degree of entanglement can be tuned using the polaroid setting \( \varphi_{34} \). The degree of entanglement can be quantified either using Bell’s inequality or by the von Neumann entropy of the reduced density matrix after tracing over one of the subsystems (3 or 4). A straightforward calculation of the von Neumann entropy shows that it does depend on the geometric phase. Since the geometric phase is achromatic, we can apply the same phase over all the frequencies in the band of interest by tuning \( \varphi_{34} \) and generate entangled photon pairs with a degree of precision.
and control. This setup can be used as a source of entangled photon pairs for other experiments probing quantum entanglement.

The Three-Slit Experiment: Quantum mechanics is often introduced by a discussion of the two-slit experiment in which an electron is incident on an opaque barrier with two slits and then detected when it falls on a screen. The surprise of the quantum theory is that the outcome of the two-slit experiment is not determined by the outcome of one-slit experiments in which one or the other of the slits is blocked. This is in sharp contrast to classical random processes like Brownian motion. If one considers the passage of a Brownian particle through slits $A$ and $B$, one finds that

$$P_{AB} = P_A + P_B ,$$

where $P_{AB}$ is the probability of detecting the particle when both slits are open and $P_A$ and $P_B$ are the corresponding detection probabilities in one-slit experiments. Thus classical probabilities are one slit separable, but quantum probabilities are not: the equality above is not satisfied in the two slit quantum experiment.

However, if one considers three slits $A, B, C$, one finds that in quantum mechanics, the outcome of the three-slit experiment is determined by the outcomes of the one and two slit experiments. Mathematically,

$$P_{ABC} = P_{AB} + P_{BC} + P_{CA} - P_A - P_B - P_C ,$$

which follows easily from writing $P_{ABC} = |\psi_A + \psi_B + \psi_C|^2$ and $\psi_A, \psi_B, \psi_C$ are the amplitudes for passage through the slits. Thus quantum mechanics is two slit separable [15]. This is why we do not find a discussion of the three-slit experiment in elementary Quantum Mechanics books: it brings in nothing new.

The situation changes when one considers multiparticle and nonlocal processes of the kind exemplified by our experiment of Fig. 1. Consider a three-slit experiment in which three incoherent beams of light fall upon three slits $A, B, C$ which are covered by analysers $P_A, P_B, P_C$ each of which allows a single state on the Poincaré sphere to pass. The light from the analysers is then allowed to fall on three unpolarised detectors labelled 4, 5, 6. By considerations similar to our analysis of the experiment of Fig. 1 we find that the number correlations $\langle N_4 N_5 N_6 \rangle$ contain terms involving the geometric phase (half the solid angle subtended by the three polarisation states $A, B, C$ of the analysers). Such an effect is not present in any of the two-slit or one-slit experiments, since two (or fewer) points on the Poincaré sphere do not enclose a solid angle. The effect is a genuinely three slit effect, not decomposable in terms of two and one slit effects. Thus quantum theory contains effects which are not two slit separable because of multiparticle entanglement. Our three slit experiment involving the geometric phase brings out this point forcefully.

The question of whether a single particle crossing a barrier with slits obeys two slit separability is ultimately an experimental one. The theoretical possibility of violations of two slit separability in such experiments was noted by Sorkin [13], who proposed that there may be theories going beyond quantum mechanics which admit such effects. There have been attempts [16] to search for such effects in a three slit experiment using photons. Since these experiments are null experiments, one has to be careful to rule out all possible three slit effects that are present due to multiparticle entanglement. Geometric phase effects which involve three photons are an example of such three slit effects. The experiment we propose here in Fig. 1 is just the simplest of a class of phenomena involving multiparticle entanglement, nonlocality and the geometric phase. We hope to interest the quantum optics community in pursuing these ideas further.

It is a pleasure to thank Urbasi Sinha for discussions related to the three-slit experiment, Anders Kastberg for discussions on a possible experimental realisation and Hema Ramachandran and R. Srikanth for discussions on entanglement.
