Abstract
Introduction: Western studies have explored post-bariatric patients concerning their views on excess skin and body contouring surgery (BCS), but Asian data were lacking. This study aims to investigate the experience of excess skin and attitude to BCS of a Chinese post-bariatric population. Methods: A total of 210 Chinese patients who underwent bariatric surgery from March 2015 to September 2018 were cross-sectional studied using the Sahlgrenska Excess Skin Questionnaire and a study-specific questionnaire. Results: The survey response rate was 61.4%. Most responders (78.2%) reported they had excess skin, and the most common sites were the abdomen (70.2%) and the upper arms (61.3%). Most responders (66.1%) reported being bothered by impaired health-related quality of life (HRQoL), and the most common problem was “the feeling of having unattractive body appearance” (42.7%). Many patients (37.9%) desired for BCS, and “the impact of excess skin is not serious enough” was the reason why not undergoing BCS being chosen most (28.1%), then “the cost is too high” (20.2%) and “worrying about the risk or complications of BCS” (18.4%). Younger age, female gender, higher weight loss, having full-time job, and earning higher income were independent factors increasing their desires for BCS. Conclusions: Most Chinese post-bariatric patients have excess skin and are bothered by impaired HRQoL. The abdomen and upper arms are the sites where patients are most seriously affected and most eager for BCS. The conservative attitude toward BCS and the cost without reimbursement are the main barriers.

Introduction
Obesity (body mass index [BMI] \( \geq 30 \text{ kg/m}^2 \)) is one of the greatest public health issues in many countries, and its prevalence is increasing rapidly worldwide in recent decades [1]. Obesity increases the risk of comorbidities such as diabetes mellitus, hypertension, hyperlipidemia, obstructive sleep apnea, and cardiovascular diseases that

Zhiyuan Jiang and Guixiang Zhang contributed equally to the research.
all affect human health and reduce life expectancy [2, 3]. According to the Endocrine Society Scientific Statement on the Science of Obesity Management, programs that are effective for weight loss include peer-reviewed and approved lifestyle modification programs, diets, commercial weight loss programs, exercise, medications, and surgery [4]. By changing the anatomy and physiology of the gastrointestinal tract, bariatric/metabolic surgeries such as sleeve gastrectomy and Roux-en-Y gastric bypass impact appetite, eating behavior, metabolism, energy expenditure, and other mechanisms to produce substantial weight loss and improve obesity-related comorbidities [2, 3, 5, 6]. In comparison with Caucasians with the same BMI, Asians have a higher percentage of body fat and visceral fat, which has predisposed Asians to insulin resistance and the development of type 2 diabetes and associated metabolic disorders at lower BMI levels [7]. As a result, a need for bariatric surgery is becoming apparent for Asian patients with obesity [8].

Although weight loss following bariatric surgery is almost beneficial, it also involves adverse effects; the main downside is the excess skin which could develop in many body parts [9]. It is not uncommon for post-bariatric patients to report a high level of dissatisfaction with excess skin which leads to social withdrawal, physical discomfort, psychological issues and, eventually, impairments to health-related quality of life (HRQoL) [10–12]. The problems related to excess skin cannot be completely resolved by modifications in lifestyle, or physical exercise [13], while body contouring surgery (BCS) which refers to a series of plastic procedures aiming to eliminate excess skin and adipose tissues seems to be the only solution to be effective [14, 15]. According to the latest available global statistics from the International Society of Aesthetic Plastic Surgery, surgical procedures involving the body and extremities, such as abdominoplasty, buttock lift, and lower body lift, increased by 7% within just 1 year, reaching almost 3.5 million surgeries performed annually [16].

Quite a few clinical studies focused on the post-bariatric excess skin, some assessed predictors of BCS utilization in bariatric patients and reported the prevalence of BCS, and some evaluated the effect of BCS on excess skin-related symptoms, and some described the desire for as well as barriers to BCS [16–21]. Also, several systematic reviews and meta-analyses confirmed the positive effects of BCS on HRQoL and concluded that most post-bariatric patients desired BCS [13, 22, 23]. However, all these studies were carried out in Western developed countries and taken the Caucasian race as the main object, thus lacked data from developing countries (running different health insurance policies) and Mongolians (having different skin characteristics). Collectively, the present cross-sectional study was designed to investigate the experience of excess skin of Chinese post-bariatric population and their desire for as well as barriers to BCS.

Materials and Methods

Study Design and Patients

This is a cross-sectional study among the patients of our prospective database. The database starts on March 2015 and enrolls patients who underwent bariatric surgery at the department of Gastrointestinal Surgery of West China hospital. The inclusion criteria of patients in this study are as follows: (1) Mongolians with Chinese nationality; (2) undergoing bariatric surgery before September 2018; (3) no experience of massive weight loss (MWL) [24] before bariatric surgery; (4) contact can be made through WeChat; and (5) not suffering from any malignant tumor or disabling disease. A total of 210 patients were identified eligible and then were sent a questionnaire survey in October 2020 via WeChat-based electronic questionnaire platform (Wenjuanxing, http://www.wjx.cn/). Before starting the questionnaire, patients gave electronic informed consent. Patients were asked to fill in their real name, age, preoperative weight and approximate time of bariatric surgery in the questionnaires so that we could make sure that the questionnaires were written by themselves, and only when these basic information of a questionnaire matches with that in the database, it is regarded as an effective response. The patients who did not reply were sent the same questionnaire a second time 2 weeks later. Each patient can submit the questionnaire only once, and the submitters of effective responses were considered as responders. Variables including nationality, race, gender, degree of education, follow-up, baseline body height, baseline body weight, type of bariatric procedure, comorbidities with obesity, and complications of bariatric surgery were collected from the database.

Questionnaires

Chinese version Sahlgrenska Excess Skin Questionnaire (SESQ) Following the format and structure of its original version, we translated the SESQ into Chinese for the first time. The Chinese version SESQ also contains 29 questions divided into 3 parts: Part 1 contains several questions concerning demographic data; Part 2 includes assessment of symptoms caused by excess skin (HRQoL); and Part 3 includes questions about the amount and degree of discomfort from excess skin on specific parts of the body.

Study-Specific Questionnaire

The study-specific questionnaire was constructed in order to: (1) obtain more detailed general information such as educational level, employment, complications of bariatric surgery, and chronic diseases and (2) determine the prevalence of BCS, desires for BCS, and the reasons not undergoing BCS of our post-bariatric patients.

Statistical Analyses

Descriptive statistics are given as mean and SD, as median and range, or as number and percentage. Continuous variables in the different groups were tested for normal distribution using the Kruskal-Wallis normality test. The independent-sample t and the
Mann-Whitney U tests were used for the data subject to normal distribution and abnormal distribution, respectively, for comparisons between different groups. Categorical variables were assessed using the Pearson χ² or the Fisher exact test, as appropriate. The pairwise correlation among the percent of total body weight loss (%TWL), the amount of excess skin, and the impairments to HRQoL were analyzed using Spearman's rank correlation coefficient. Multivariable logistic regression analysis was performed to determine independent factors associated with desire for BCS. p value ≤0.05 (2-sided) was considered to indicate a statistically significant difference. All statistical analysis was performed with SPSS 25 statistical software (IBM Corporation, Armonk, NY, USA).

Results

Basic Characteristics of Study Population

Of 210 eligible patients, 129 (61.43%) responded effectively and were counted as study population. The majority of the study population were adults and female, and only 4 were adolescent at the time of bariatric surgery. Most of them received higher education, 54 (41.86%) had bachelor’s degrees, and 12 (9.30%) got master’s or doctoral degrees. Most of them (78.29%) were employed, and 96 (74.42%) patients earned 120,000 RMB or less. Only 3 (2.33%) patients did not reach MWL after surgery with %EWL being 42.93, 44.92, and 43.86%, respectively. Of the study population, only 3 females and 2 males underwent a total of 8 BCS procedures, including 4 performed in the abdomen, 3 in the upper arms and 1 in the chin. According to the grouping of female and male, there was no statistical difference in baseline BMI, current BMI, pre-bariatric impaired glucose tolerance or type 2 diabetes, type of bariatric surgery, employment, and prevalence of BCS. The details of basic characteristics are listed in Table 1.

| Characteristic                        | Female (n = 75) | Male (n = 54) | Total (n = 129) | p value* |

Table 1. Basic characteristics of study population
Experience of Excess Skin

The experiences of excess skin of 124 patients who had not received any post-bariatric BCS were studied; results are shown in Figure 1 and online suppl. Table 1; see www.karger.com/doi/10.1159/000517587 for all online suppl. material. Most of responders (83.33% of females and 71.15% of males) reported they had excess skin. Females expressed higher proportions of having excess skin than males, with statistically significant differences \( p < 0.05 \) in most sites except for the chin and buttocks. The most frequently reported sites of having excess skin in both genders were the abdomen (79.17% in female and 57.69% in male), followed by the upper arms (75.00% in female and 42.31% in male). For the responses that estimated the amount of excess skin as “very much” or “a lot,” the abdomen was the most common site in females (16.67%) and busts the most in males (7.69%).

The findings concerning the impairments to HRQoL due to excess skin are shown in Figure 2 and online suppl. Table 2. 66.67% of females and 65.38% of males reported being bothered by impaired HRQoL. The most common problem was the feeling of having unattractive body appearance (47.22% in female and 36.54% in male). The males reported higher proportions in “pain in upper back” and “hindrance in intimate situations” than females \( (p = 0.031 \text{ and } 0.036, \text{ respectively}) \), while female patients had more “difficulties to find clothes that fit” \( (p = 0.026) \). No statistical difference was found in the remaining 7 examined dimensions between men and women \( (p > 0.05) \).

Attitude to BCS

Of the 124 patients who had not undergone any BCS procedure, 47 (37.90%) expressed a desire for BCS, and in detail, 57.45% of them rated their desires as “occasional-
Chinese Patients’ Experience of Excess Skin

Multivariable analyses suggested that younger age, female gender, higher %TWL, having full-time job and earning higher annual income were independent factors of patients’ desires for BCS (Table 2). Thirty-eight patients responded the question of “the top 3 body parts you want most to undergo BCS” and reported 87 body parts, of which the “abdomen” was chosen 32 times (36.78%), followed by the “upper arms” 18 times (20.69%), the “thighs” and “breasts/chest” both 17 times (19.54%), and finally the “waist” 3 times (3.45%). At the first blank of the top 3 body parts, 14 patients chose the “abdomen,” 12 the “breasts/chest,” 9 the “upper arms,” and 3 the “thighs.”

Sixty-four patients reported a total of 114 reasons why not undergoing BCS (Fig. 3). “The amount of excess skin or its impact on HRQoL is not serious enough to require BCS” was the reason chosen for the most, up to 32 times. “Thinking that the cost is too high” and “worrying about the risk, complications or surgical scars brought by BCS” were 2 common reasons chosen by more than 20 times, respectively. More than 10 patients either thought that they needed more information before making a decision or planned to undergo BCS in the near future.

Discussion

To the best of our knowledge, this study is the first one to investigate the experience of excess skin and attitude to BCS of Asian post-bariatric patients. Previous studies suggested that a major weight loss occurred within the first year after bariatric surgery [25, 26], and BCS was often deferred until 18 months to ensure weight stability [27], thus we enrolled patients who had underwent bar-

iatriate surgery more than 24 months in the hope that the body weight of the most and the troubles caused by excess skin had stabilized, and the attitudes toward BCS surgery had been mature.

There had been no specific instrument in Chinese for evaluating post-bariatric patients’ experience of excess skin. After browsing a number of quality-of-life measurement instruments for bariatric and BCS, we finally chose the SESQ which was regarded as the most suitable one by all team members and translated it into Chinese. SESQ is the first questionnaire to evaluate excess skin from the patient’s point of view and its test-retest reliability as well as validity have been proved to be good [28].

E-mail is not popular among Chinese ordinary people, a considerable number of them do not have an e-mail address, and the proportion of them who regularly use it to deal with personal affairs is very low. Therefore, WeChat known as the social software most used by Chinese people was chosen for our study. We imported the content of our questionnaire into a network platform (Wenjuanxinxing, http://www.wjx.cn/), through which a QR code link associated with this questionnaire was established. The QR code can be shared through WeChat, and patients who receive it are able to fill out the questionnaire immediately. Before releasing the QR code, we first evaluated the convenience of the whole process of answering the questionnaire, and then invited several patients to evaluate its readability and understandability. Then, we made several improvements and distributed the final version to all eligible patients. Within 2 weeks, we received 91 valid responses, and after sending a reminder, we received another 38 ones, thus adding up to 129 responders, with a response rate of 61.43% which was about the same as that of similar Western studies that surveyed patients via e-mail [29].

The World Health Organization identified for Asian populations potential public health action points of BMI ≥23 kg/m² (increased risk) and BMI ≥27.5 kg/m² (high risk) [30]. The median of %EWL of this study population was 92.37%, and 97.67% of them reached MWL, which not only showed the well effect of bariatric procedures to these people, but also affirmed the characteristics of their body weights from the side, that is, they were mainly with class I and II obesity. After all, because of the peculiarity of obesity in Asians (higher percentage of visceral adipose tissue) and their vulnerability to insulin resistance [31], they may consider receiving surgical intervention when with lower BMI than western counterparts.

To rule out the effect of BCS, we excluded 5 patients who had undergone BCS before surveys when analyzing experiences of excess skin. The results showed that like Western studies, most Chinese patients developed more or less excess skin in some area of the body, and reported being bothered by impaired HRQoL. Generally, females were more likely to develop excess skin, and the prevalence of excess skin in the abdomen, upper arms, inner thighs, and breasts/chest were all more than half. For the responses that estimated the amount of excess skin as “very much” or “a lot,” the abdomen was also the most common site reported to have the most severe degree of excess skin, which agreed basically with the results of other studies [10, 28]. The proportion of patients suffered from the impairments to HRQoL was not as high as that of feeling excess skin, even the most common symptom caused by excess skin “unattractive body appearance” occurred in less than half in both sexes. Even if the proportions were not equal, a strong correlation ($r = 0.668, p < 0.0001$) was found between the amount of excess skin and the impairments to HRQoL, indicating that the excess skin is an important factor in determining the HRQoL; details can be found in online suppl. Table 3.

The urgency of obtaining BCS was not as intense as in Western studies with <40% patients expressing expectations for BCS. As for the reasons why not undergoing a BCS procedure, unlike Western patients that often listed “cost” or “lack of reimbursement” in the first place, “the impact of excess skin is not serious enough to require BCS” was chosen by the half of 64 responders. The above 2 points revealed these patients’ more conservative attitude toward BCS. In addition, 23 responders said they gave up BCS because of the high costs; Western developed countries could reimbursed patients’ part or all of the BCS expenses [15, 17, 32], but the Chinese basic medical insurance and all commercial insurances both list BCS as a purely cosmetic surgery and refuse coverage, which further reduces the desire for BCS and prevalence of BCS. At last, there were quite a few patients who had no idea concerning whether BCS could alleviate excess skin-related problems, and worried too much about the scars or surgical risks caused by BCS, which likely suggests that both bariatric and plastic surgeons should correctly promote BCS in clinical practice.

Previous works have shown that women, those of younger ages, those with a greater change in BMI, and those with poorer psychosocial self-report scores were associated with desiring BCS and pursuit of BCS after bariatric surgery [9, 12]. Not quite similar to their results, multivariable analysis in the current investigation revealed that variables were identified as independent factors to increase patients’ desires for BCS including young-

DOI: 10.1159/000517587
er age, female gender, and higher %TWL as well as having full-time job and earning higher personal annual income. The reason why the last 2 variables are included may be related to the fact that all expenses of a BCS procedure could be paid only out of patient’s own pocket in China, thus the patients with full-time jobs and higher incomes have more initiative in deciding whether or not to undergo BCS.

Though the present study adopted strict inclusion criteria for eligible patients and valid responders, conducted with rigorous statistical analysis, and obtained the firsthand information concerning the experiences of excess skin of Asians patients, it has some limitations. First, this study was limited by cross-sectional design, which provided the evidence not at the highest quality. Second, the survey was administered only once at patients’ 2 to 4-year postoperative time points, so the impact of heterogeneity of follow-up time on the results cannot be ruled out, studies have pointed out that patients’ attitudes towards excess skin and BCS changed over time [27]. Third, we used self-translated and self-made questionnaires and did not physically examine or measure the patients, therefore, we could obtain no raw data that can be matched and compared with that of other researches. The fourth point was the lack of data from nonresponders, patients with greater problems with excess skin are more likely to respond to this survey than those with less problems, thus we are at a risk of over-interpretation of the results. At last, the proportion of individuals who underwent BCS was very small so that we could not explore the differences about excess skin and HRQoL that may exist between those who did and did not undergo BCS.

**Conclusion**

Most Chinese post-bariatric patients especially females have excess skin in one or more body parts, and many of them are bothered by impaired HRQoL due to excess skin, which can be seen in aspects of physical symptoms as well psychosocial function. However, the desires for BCS are not as intense as reported in Western studies, and attitudes toward BCS are more conservative. Also, the higher cost lacking any reimbursement is another important barrier to obtaining BCS. The abdomen and upper arms are the sites where Chinese patients are most likely to have excess skin, are most seriously affected by it, and are most eager for BCS as well as are the sites where the most BCS procedures have been performed. Younger age, female gender, higher weight loss, having full-time job, and earning higher personal annual income were independent factors increasing patients’ desires for BCS. Few studies have focused on excess skin issues of Asian post-bariatric patients, and more research attention is needed here.

**Statement of Ethics**

This research protocol was approved by West China Hospital of Sichuan University Biomedical Research Ethics Committee (No. 2020137). All procedures performed in this study involving human participants were in accordance with the 1964 Declaration of Helsinki and its later amendments. Only patients who view and confirm the electronic informed consent on the home page of the questionnaire can continue to complete it, so all the valid questionnaires are in line with the principle of informed consent.

**Conflict of Interest Statement**

The authors have no conflicts of interest to declare.

**Funding Sources**

This study was supported by the Wu Jieping Medical Foundation (320.2710.1810) and 1.3.5 project for disciplines of excellence, West China Hospital, Sichuan University (ZYJC18034).

**Author Contributions**

The original idea of this research was conceived by Z. Jiang, B. Zhang, and Z. Cheng. Z. Jiang and G. Zhang recruited patients, distributed the questionnaires, collected and analyzed data, and drafted the manuscript. X. Du., Y. Chen., C. Shen., and Z. Cai. were actively involved in questionnaire translation and design, statistical analysis, data interpretation, and contributed to the discussion. B. Zhang and Z. Cheng supervised the work and had full access to all the data in this study and takes responsibility for the integrity as well as the accuracy of the data. All the authors approved the final version of the manuscript.
