Abstract

Lipid production in microalgae is highly dependent on the applied light intensity. However, for the EPA producing model-diatom *Phaeodactylum tricornutum*, clear consensus on the impact of incident light intensity on lipid productivity is still lacking. This study quantifies the impact of different incident light intensities on the biomass, TAG and EPA yield on light in nitrogen starved batch cultures of *P. tricornutum*. The maximum biomass concentration and maximum TAG and EPA contents were found to be independent of the applied light intensity. The lipid yield on light was reduced at elevated light intensities (>100 μmol m⁻² s⁻¹). The highest TAG yield on light (112 mg TAG mol⁻¹) was found at the lowest light intensity tested (60 μmol m⁻² s⁻¹), which is still relatively low to values reported in literature for other algae. Furthermore, mass balance analysis showed that the EPA fraction in TAG may originate from photosynthetic membrane lipids.

Introduction

Lipid production by phototrophic microalgae is only economically feasible today for high-value products, such as pigments and ω-3-fatty acids [1]. One of the major hurdles for commercial bulk microalgal lipid production is the low lipid yield on light [1–3].

Typically, microalgal lipid production is induced by nitrogen deficiency. When exposed to nitrogen deficient conditions, some microalgal species can accumulate triacylglycerol (TAG) up to 30–60% of dry weight [4–6]. However, nitrogen deficiency is often accompanied with impaired or even fully inactivated photosynthesis [4,7] and therefore results in a reduced TAG yield on light. For commercial production of TAGs, the TAG yield on light should be increased.

One of the most advertised microalgae for commercial lipid production is *Phaeodactylum tricornutum*. *P. tricornutum* is a salt-water diatom that is already cultivated at large scale for aquaculture. This microalgae produces large amounts of eicosapentaenoic acid (EPA; a long chain polyunsaturated fatty acid) and can produce TAG up to 30% of dry weight [4]. It is...
generally acknowledged, however, that high light exposure can severely affect the biomass and lipid productivity of this diatom [8–12]. However, clear consensus regarding the impact of light intensity on TAG and EPA productivity in *P. tricornutum* is still lacking. The aim of this work is to obtain insight in the relation between incident light intensity and the accumulation of TAG and EPA under nitrogen starvation.

**Material and methods**

**Strain, medium and precultivation**

*Phaeodactylum tricornutum* SAG1090-1b was obtained from the Culture Collection of Algae Goettingen University, Germany. Cultures were maintained in 250 mL shake flasks containing 100 mL filter sterilized (pore size 0.2 µm) medium. The medium was designed to reach a biomass concentration of 2.5 g L⁻¹ and consisted out of 252 mM NaCl, 16.8 mM KNO₃, 3.5 mM Na₂SO₄, 5 mM MgSO₄ 7H₂O, 2.4 mM CaCl₂ 2H₂O, 2.5 mM K₂HPO₄, 10 mM NaHCO₃, 28 µM NaFeEDTA, 80 µM Na₂EDTA 2H₂O, 19 µM MnCl₂ 4H₂O, 4 µM ZnSO₄ 7H₂O, 1.2 µM CoCl₂ 6H₂O, 1.3 µM CuSO₄ 5H₂O, 0.1 µM Na₂MoO₄ 2H₂O, 0.1 µM Biotin, 3.7 µM vitamin B1 and 0.1 µM vitamin B12. The medium contained 100 mM, 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonic acid (HEPES) as a pH buffer. Prior to cultivation, the pH was adjusted with KOH to pH 7.2.

Cultures were maintained in a cultivation chamber at 25°C, orbitally shaken at 120 rpm, illuminated at an incident light intensity of 40–60 µmol m⁻² s⁻¹ and a 16:8h light:dark (LD) cycle under enriched air (2% CO₂). Three days prior to the start of the experiment, cultures were transferred to an orbital shaker incubator with an incident light intensity of 160 µmol m⁻² s⁻¹, 16:8h LD cycles and 2.5% CO₂ enriched air.

**Photo bioreactor setup and operation**

Experiments were performed in aseptic, flat-panel, airlift-loop reactors (Algaemist, Technical Development Studio, Wageningen University, the Netherlands). The reactor has a working volume of 400 mL, a light path of 14 mm and an illuminated area of 0.028 m² (Schematic illustration of the reactor design is given in Breuer et al. [9]). Illumination was provided using 6 LED lamps with a warm white light spectrum, (BXRA W1200, Bridgelux, USA, emission spectrum given in the S1 Fig) under a 16:8h LD cycle. The incident photon flux density (PFD in) was measured with a LI-COR 190-SA 2π PAR (400–700 nm) quantum sensor (PAR, USA) and determined as the average over 28 points evenly distributed over the illuminated surface of the inside of the front glass panel of the reactor. The culture was continuously supplied with sterile moisturized air at 0.4 L min⁻¹, pH was maintained at 7.2 by on-demand sparging of CO₂ to the airflow and temperature was kept constant at 20°C. Reactor medium was similar to the preculture medium, with modifications to the amount of KNO₃ (5 mM instead of 16.8 mM) and exclusion of HEPES. 5 mM of KNO₃ is sufficient to reach a biomass concentration of 1.2 g L⁻¹ (assuming a cellular nitrogen fraction of 10% per dry weight, measurements not shown). Per day, a maximum of 2 drops of 1% (v/v) antifoam (Antifoam B, J.T. Baker) were added manually to the reactor when foaming was visible.

Reactors were heat sterilized (60 min at 121°C) and inoculated at a biomass concentration of approximately 0.5 g L⁻¹ of dry weight and grown at an incident light intensity of 100 µmol m⁻² s⁻¹. Once the biomass concentration reached 1 g L⁻¹, which was typically three days after inoculation, the set points for incident light intensity were changed to the desired values (60, 100, 250, 500, or 750 µmol m⁻² s⁻¹ incident light intensity). The day at which the light intensity was changed to the experimental set point was regarded as start of the experiment, and therefore referred to as t = 0. Periodically, samples (approximately 20 mL culture volume) were
taken aseptically and analysed for dry weight concentration, triacylglycerol (TAG) and total fatty acid (TFA) concentration and composition, dissolved (residual) nitrate Photosystem II (PSII) maximum quantum yield ($F_{v}/F_{m}$) ratio, and absorption cross section. After taking a sample, the culture volume was restored by adding 0.2 μm-filtered reactor medium to ensure that the pH probe remained submerged. Depending on whether the culture was in N-replete phase or N-depleted phase, this medium contained either 5 mM KNO$_3$ or no nitrogen, respectively.

Five different incident light intensities were selected that cover both low light and light saturation (light saturation point for *P. tricornutum* was found at 150–200 μmol m$^{-2}$ s$^{-1}$ [13–15]). Three photo bioreactor experiments were conducted in biological duplicate to test reproducibility[16].

Measurements for dry weight, $F_{v}/F_{m}$ and dissolved nitrogen were performed in technical triplicates. Measurements for the light absorption spectrum, lipid content and composition were performed in technical duplicate.

**Biomass analysis**

Samples were taken at regular time points to monitor biomass dry weight concentration gravimetrically as described by [17]. Light absorption spectrum was measured in a double-beam spectrophotometer (UV-2600, Shimadzu, Japan) equipped with an integrated sphere (ISR-2600). The average dry weight-specific optical cross section ($\alpha_c$ in m$^2$ g$^{-1}$) was calculated from the obtained absorption spectrum as described by [18]. The $F_{v}/F_{m}$ ratio was measured using an AquaPen-C AP-C 100 FluorPen fluorometer (Photon Systems Instruments, Czech Republic) equipped with an orange LED emitter (excitation light 620 nm) as described by [19].

The triacylglycerol (TAG), membrane lipid (ML) and total fatty acid (TFA) content and fatty acid composition were determined by lipid extraction (chloroform:methanol mixture), lipid class separation using a silica column, transesterification and subsequently quantified using gas chromatography (GC-FID) as described by Breuer et al. [9]. The dissolved nitrate concentration was measured with an AQ2 nutrient analyser (Seal Analytical, USA) as described by Benvenuti et al. [20].

**Calculating yield and productivity**

The time averaged volumetric productivity ($r_i(t_0 \rightarrow t)$) was calculated by dividing the amount of formed product (i: biomass, triacylglycerol, EPA) over cultivation time according to Eq 1;

$$r_i(t_N \rightarrow t) = \frac{C_i(t) - C_i(t_N \rightarrow 0)}{t - t_N \rightarrow 0}$$

The time averaged yield of TAG on light ($Y_{TAG,ph}(t_0 \rightarrow t)$) on each time point was calculated by dividing the amount of TAG produced in that period by the amount of light supplied in that period [21]. In addition, the photon costs for initial biomass production until nitrogen depletion were incorporated by assuming that this biomass was made with a theoretical net photosynthetic yield, $Y_{x,ph}$, of 1 g mol$^{-1}$ph,

$$Y_{TAG,ph}(t) = \frac{TAG(t) - TAG(t_N \rightarrow 0)}{I_0(t_0 \rightarrow t) + \frac{C_{x,ph}(t_N \rightarrow 0)}{Y_{x,ph}}}$$

In Eq 2, TAG(t) and TAG($t_N = 0$) represent the TAG concentration at time point t and the moment of nitrogen starvation, respectively. The exact time of nitrogen starvation ($t_N = 0$) was estimated by interpolation of the biomass concentration to 1.2 g L$^{-1}$. $I_0$ is the incident light.
Results and discussion

Effect of light on biomass growth

The impact of five different light intensities on biomass, TAG and EPA productivity during nitrogen starvation was assessed in batch-wise operated flat-panel photo bioreactors that were subjected to 16:8h light:dark (LD) cycles. Results for dry weight, quantum yield and TAG content are shown in Fig 1.

Sufficient nitrogen was added to reach a biomass concentration of 1.2 g DW L⁻¹. After that biomass concentration was reached, all nitrogen was used and the culture was exposed to nitrogen starvation. The biomass concentration further increased up to 2.2 g L⁻¹ of dry weight, which was due to the accumulation of TAG (Fig 1) and carbohydrates (S1 Table). The maximum achieved biomass concentration was reached 5 days after nitrogen starvation started, except for the culture exposed to the lowest light conditions, which reached the maximum biomass 14 days after nitrogen starvation started. The maximum reached biomass concentration was 2.15±0.1 g L⁻¹, independent of the supplied light intensity (Fig 1A). Other studies showed similar findings for the freshwater microalgae *Acutodesmus obliquus* under nitrogen starvation [4].

Cultures that are light limited are expected to show an increase in biomass productivity upon increasing light intensities [9]. However, our results show no differences in productivities for the cultures exposed to 100 μmol m⁻² s⁻¹ and higher (Fig 1). This similarity in productivity might be explained by photo inhibition that occurred from 100 μmol m⁻² s⁻¹ onwards. As soon as the photosynthetic machinery becomes inhibited, further increasing light intensity would not enhance the productivity anymore [22]. According to Fig 1B, a strong decline in Fv/Fm was observed (from 0.6 to 0) for cultures exposed to light intensities above 100 μmol m⁻² s⁻¹ immediately after nitrogen starvation. A decline in Fv/Fm is generally acknowledged with reduced photosynthetic efficiency or photo damage [19,23,24]. Geider et al. [13] presented a light curve for *P. tricornutum*. Similar to our findings, they reported that from 100 μmol m⁻² s⁻¹ onwards light saturation occurs in *P. tricornutum*. In addition, Acien Fernández et al. [25] performed outdoor growth experiments with *P. tricornutum*, where the maximum biomass productivity was reached at average irradiances of 50–150 μmol m⁻² s⁻¹ and decreased at light intensities higher than 150 μmol m⁻² s⁻¹. Altogether, it is likely that in this work *P. tricornutum* becomes photo inhibited at light intensities above 100 μmol m⁻² s⁻¹.

Changes in TAG accumulation, productivity and yields

Independent of incident light intensity, the TAG concentration increased from 0.05 g L⁻¹ (3% of dry weight) under nitrogen replete conditions to ~0.41 g L⁻¹ (~25% of dry weight) after prolonged nitrogen starvation (Fig 1 and S2 Table). These maximum TAG contents are in agreement with observations from literature (Table 1).

Except for the culture exposed to the lowest light intensity (60 μmol m⁻² s⁻¹), TAG accumulation did not differ significantly for the tested conditions (Fig 1). The culture exposed to high incident light intensity (750 μmol m⁻² s⁻¹) showed a decline in TAG content from day 11 onwards, which might indicate photo damage or even cell death.

The TAG yield on light is directly proportional to areal productivity and is therefore also strongly related to investment and variable production costs. The maximum time-averaged TAG yield on light is often used as indicator to determine optimal harvest moments [7]. Our study shows that large differences were observed in the maximum time-averaged TAG yield.
on light among the different tested incident light intensities (Fig 2). Of all tested conditions, the cultures exposed to low light (60 μmol m$^{-2}$ s$^{-1}$) reached the highest maximum TAG yield on light (112 mg TAG mol$_{ph}^{-1}$). Increasing the incident light intensity only resulted in lower TAG yields on light: 96 mg TAG mol$_{ph}^{-1}$ for the culture exposed to 100 μmol m$^{-2}$ s$^{-1}$ and 

https://doi.org/10.1371/journal.pone.0175630.g001
36–48 mg TAG mol\textsubscript{ph}\textsuperscript{-1} for cultures exposed to even higher light intensities. In comparison with other studies (Table 2), \textit{P. tricornutum} shows relative low TAG yields on light compared to other strains at similar or higher incident light intensities.

Sustained biomass productivity upon nitrogen starvation is a key selection parameter for efficient TAG production. As shown in Fig 1A, \textit{P. tricornutum} only showed a 2–2.2-fold biomass increase upon nitrogen starvation. Other oleaginous green microalgae (e.g. \textit{Acutodesmus obliquus}, \textit{Chlorella zofingiensis}) showed a 6–8 fold increase in biomass upon nitrogen starvation [4,5,19]. High photon to TAG conversion yields are only possible when light energy is efficiently used to fix carbon (e.g. measured as biomass productivity) and when the majority of fixed carbon is channelled towards storage lipids (e.g. TAG content). Literature reports that diatoms are specifically known to mobilize alternative electron transport (AET) pathways, that can eradicate up to 50% of the electrons released by PS II [28–30]. Also, increased Non-Photochemical Quenching (NPQ) rates were found for \textit{P. tricornutum} when exposed to

![Fig 2. Time averaged TAG yield on light for five different incident light intensities over time. Incident light intensities of 60 \mu mol m\textsuperscript{-2} s\textsuperscript{-1} (blue circles), 100 \mu mol m\textsuperscript{-2} s\textsuperscript{-1} (red squares), 250 \mu mol m\textsuperscript{-2} s\textsuperscript{-1} (green triangles), 500 \mu mol m\textsuperscript{-2} s\textsuperscript{-1} (black circles) and 750 \mu mol m\textsuperscript{-2} s\textsuperscript{-1} (open diamonds). Sufficient nitrogen was added to reach biomass concentrations of 1.2 g L\textsuperscript{-1}, thereafter cells were exposed to nitrogen starvation. Error bars indicate the standard deviation of both cultures from the average value.](https://doi.org/10.1371/journal.pone.0175630.g002)
increased light intensities [31–33]. Both processes are known to protect the cells from photo inhibition but to also result in inherent productivity losses. For *P. tricornutum*, these mechanisms might explain the reduced photosynthetic efficiency compared to other microalgae under low light nitrogen starvation.

Considering the abovementioned light sensitivity of *P. tricornutum* during nitrogen starvation, precautions should be taken to prevent the culture from extensive photo inhibition when working in high irradiance conditions [34]. Examples are to increase the culture cell density to create a dark zone in which the photo inhibitory damage can be repaired [35,36] or to execute strain improvement for reduced antenna size [37,38].

**FA composition**

The fatty acid composition of TAG and membrane lipids (ML) did not substantially change over time nor with incident light intensity (the complete fatty acid composition of both fractions during the time-course of the experiments can be found in Table 3). The most abundant fatty acids in TAG were found to be C16:1 (44% of total TAG fatty acids) and C16:0 (30% of total TAG fatty acids). Only a small fraction of C20:5 (EPA) was found in the TAG pool (6–10% of total TAG fatty acids). The membrane lipid fraction was primarily comprised of C16:0 (20% of total ML fatty acids), C16:1 (25–30% of total ML fatty acids) and C20:5 (25–30% of total ML fatty acids) (Table 3). Literature reports similar fatty acid profiles in *P. tricornutum* [4,43–45]. As a consequence of TAG accumulation (Fig 1) and the lower EPA content of TAG compared to membrane lipids, the EPA fraction of the total fatty acid pool in the biomass dropped from 25% to 9% of the total fatty acids (S3 Table). Because the biomass productivity declined at the onset of nitrogen depletion, EPA productivity was highest (6–12 mg L\(^{-1}\) day\(^{-1}\)) under nitrogen replete growth conditions.

https://doi.org/10.1371/journal.pone.0175630.t002
Fig 3 shows the EPA concentration per litre culture with respect to the TAG and membrane lipid fraction. Apart from a small increase until day 5, neither a substantial net synthesis nor breakdown of EPA upon N starvation is observed. However, the distribution of EPA over TAG and membrane lipids changes over time. Upon nitrogen depletion, a substantial increase in EPA distribution towards TAG can be observed. Simultaneously, we observed a decrease in EPA that was bound to membrane lipids. Therefore, we hypothesize that the EPA found in TAG under nitrogen starvation could partially be derived from EPA-containing membrane lipids that were restructured upon nitrogen depletion. Similar observations have been made for Nannochloropsis oceanica [46], Nannochloropsis oculata and Pavlova lutheri [47].

For many species, nitrogen depletion results in an inherent degradation of photosynthetic membrane lipids with simultaneous accumulation of TAG. Part of the fatty acids originating from membrane lipids could thus be used as fatty acyl donors for TAG synthesis under nutrient deprivation (Fig 3). However, detailed knowledge on the mechanisms behind carbon partitioning in microalgae under nitrogen deprivation is still lacking [47–51] and further research using $^{13}$C labelling should confirm these observations. To further improve EPA productivity by means of metabolic engineering or process development [52], it is crucial to understand the regulation of EPA towards different lipids classes (e.g. TAG or structural membrane lipids) under different environmental conditions.

EPA incorporation in membrane lipids and triacylglycerol

Table 3. Average fatty acid composition of P. tricornutum in the TAG and ML lipid fraction for five different light intensities: 60, 100, 250, 500 and 750 μmol m$^{-2}$ s$^{-1}$. Values are averaged over the entire time course of the experiment (n = 7). Standard deviations are shown between brackets.
Conclusion

Elevated light intensities (>100 μmol m⁻² s⁻¹) reduce the photosynthetic efficiency and the TAG yield on light during nitrogen starvation, likely caused by photo inhibition. Compared to other microalgae strains, relative low TAG yields on light were observed for *P. tricornutum* as the maximum yield was only 112 mg TAG mol⁻¹ phy⁻¹ (at 60 μmol m⁻² s⁻¹). TAG contents were similar for all light intensities tested (i.e. 25% of dry weight). Further analysis on the fatty acid composition revealed that the TAG fraction of *P. tricornutum* contains 6–10% of EPA. Mass balance analysis revealed this EPA fraction may originate partly from photosynthetic membrane lipids that were restructured after nitrogen depletion.
