Abstract
The goal of this study was to assess the clinical effectiveness and safety profile of the COVID-19 treatment protocol (containing both hydroxychloroquine (HCQ) and azithromycin) in an Iraqi specialised hospital.

Methods: This prospective study used a pre- and post-intervention design without a comparison group. The intervention was routine Ministry of Health (MOH) approved the management of COVID-19 for all patients. The study was conducted in a public healthcare setting in Baghdad, Iraq from March 1st to May 25, 2020. The study outcome measures included the changes in clinical and biochemical parameters during the hospitalisation period. Paired t-test and Chi-square test were used to compare the measures of vital signs, lab tests and symptoms before and after treatment.

Results: The study included 161 patients who were admitted with positive RT-PCR and clinical symptoms of COVID-19. In terms of severity, 53 (32.9%) patients had a mild condition, 47 (29.2%) had moderate condition, 35 (21.7%) had severe condition and 26 (16.1%) had critical condition. Most patients (84.5%) recovered and were discharged without symptoms after testing negative with RT-PCR, while 11 (6.8%) patients died during the study period. The signs and symptoms of COVID-19 were reduced significantly in response to a therapy regimen containing HCQ and azithromycin. The most common reported side effects were stomach pain, hypoglycemia, dizziness, itching, skin rash, QT prolongation, arrhythmia, and conjunctivitis.

Conclusions: This natural trial showed that the COVID-19 regimen containing both HCQ and azithromycin can be helpful to promote the recovery of most patients and reduced their signs and symptoms significantly. It also shows some manageable side effects mostly those related to heart rhythm. In the absence of FDA-approved medications to treat COVID-19, the repurposing of HCQ and azithromycin to control the disease signs and symptoms can be useful.
complicated by acute respiratory distress syndrome (ARDS), sepsis and septic shock, multiorgan failure, including acute kidney injury and cardiac injury. Older age and co-existing diseases have been reported as risk factors for death. On March 12, the WHO officially declared the COVID-19 outbreak a pandemic. As of June 24, 2020, COVID-19 was confirmed in 188 countries with a total confirmed cases of 9,295,365 and more than 478,289 deaths. Iraq had 36,702 confirmed cases, 16,814 recovered cases and 1,330 deaths associated with COVID-19 pandemic as of June 24, 2020.

The pandemic of COVID-19 is caused by the novel severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) and presents a challenge in regard to identifying effective drugs for prevention and treatment. Up to the time of writing this manuscript, there were no medications approved by the US Food and Drug Administration (FDA) to treat COVID-19. However, the FDA recently created a new emergency programme, the Coronavirus Treatment Acceleration Programme (CTAP), aimed at speeding up research for the development of COVID-19 treatments. As of May 11, 2020, more than 144 clinical trials had been launched to test COVID-19 treatments, including some drug repurposing or repositioning. Researchers are also testing medications typically used to treat other conditions to see if they are also effective in treating COVID-19. For example, hydroxychloroquine (HCQ) and chloroquine are two medications that have been used for many decades to treat malaria and autoimmune conditions such as rheumatoid arthritis and lupus, and azithromycin is an antibiotic commonly used to treat bacterial infections such as bronchitis and pneumonia. They have been shown to have some in vitro activity against viruses such as influenza A and Zika.

We are ethically committed to share the experience of Iraqi healthcare providers with COVID-19 treatment with the scientific community to help answer some questions about the effectiveness and safety of HCQ and azithromycin containing regimen. The Iraqi Scientific Committee at the Ministry of Health (MOH) adopted a treatment protocol on March 1st, 2020 several days after the detection of the first COVID-19 case in Iraq on February 24, 2020 (Table 1). The goal of this study was to assess the clinical effectiveness and safety profile of the current COVID-19 treatment protocol (containing both HCQ and azithromycin) in an Iraqi specialised hospital.

2 | METHODS

2.1 | Study designs, duration and setting

This prospective study used a pre- and post-intervention design. The intervention was the routine MOH approved the management of COVID-19 for all patients. In other words, this was a natural clinical trial (quasi-experiment) without any comparison group. The study was conducted in a public healthcare centre, Al-Shifaa Centre for COVID-19 pandemic treatment, Medical City, Baghdad, Iraq. The study included all adult patients with a confirmed COVID-19 infection that were admitted to this hospital over 85 days (from March 1st to May 25, 2020). They were defined as confirmed cases of coronavirus COVID-19 after the result of a nasopharyngeal sample using Reverse transcription-polymerase chain reaction (RT-PCR) comes positive.

Exclusion criteria included known allergy to hydroxychloroquine (HCQ) or chloroquine, any contraindications to HCQ or chloroquine and azithromycin including retinopathy and prolonged QT, patients with severely reduced in left ventricular (LV) function, severely reduced in renal function and G6PD deficiency in addition to pregnant and lactating women.

2.2 | Follow-up protocol and measures

The research team (clinical pharmacist and three specialist physicians) was part of the medical team in the centre. They prospectively collected patient medical information from patients, patient records and attending physicians. The information included demographics, disease and treatment characteristics and clinical outcome. Patient’s clinical conditions and routine biochemical tests were assessed at baseline and then every day to evaluate the effect of therapy protocol.

2.3 | Study outcomes

The study outcome measures were assessed at baseline (at admission) and daily after hospitalisation (post-intervention) until the discharge of the recovered patient or death. The study outcome measures included the changes in clinical and biochemical parameters during hospitalisation period such as the disappearance of clinical symptoms,
virologic clearance and occurrence of side effects. The routine assessment of vital signs was conducted three times daily. Virologic clearance was measured using real-time PCR which was retested at day 6 post hospitalisation. Complete recovery was defined as two negative RT-PCR tests (which were usually performed on days 6th and 7th of hospitalisation). Fourteen days after hospital discharge, recovered patients were retested in outpatient clinics using RT-PCR.

Other outcome measures included the time to clinical recovery (TTCR) and final clinical prognosis (recovery vs death). The TTCR is defined as the time to the disappearance of clinical symptoms (eg, cough and shortness of breath, SOB) and a normal body temperature and respiratory rate for more than 72 hours.

### 2.4 | Study patients

Study participants with confirmed cases of COVID-19 were transferred to the study specialised centre after having a positive RT-PCR test at one of the Medical City Hospitals. After admission, COVID-19 patients were classified according to clinical evaluation to mild cases (no pneumonia on a CT scan), moderate cases (pneumonia on a CT scan), severe cases (respiratory rate ≥ 30 breaths /min, oxygen saturation ≤ 93% or patients with pneumonia on a CT scan) and critical cases (respiratory failure/need mechanical ventilation). All patients were treated according to the MOH treatment protocol which relies on patient severity status (Table 1).

To assess radiological changes, a chest CT scan was conducted before starting the treatment (day 0) and after 5 days of treatment (day 6). Pulmonary status was classified into three levels: Exacerbated, unchanged, and improved. Medication safety was also assessed by monitoring adverse drug reactions (ADRs), vital signs and lab tests. Routine lab tests during the treatment period included liver function tests, renal function tests and fasting blood sugar. Liver function tests included alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP) and total bilirubin. Renal function was assessed using serum urea and
creatine (s.cr). The WHO-UPPSALA causality assessment criteria were used to determine the causality of adverse drug reactions (ADRs) of hydroxychloroquine and azithromycin.\textsuperscript{13}

All data were recorded in the patient medical record. Consent was obtained from the patients before giving the therapy regimen. The researchers de-identified patient names and addresses to keep patient confidentiality. The study was approved by the Higher Ethical Committee at Medical City Hospitals.

### 2.5 Statistical analysis

Statistical Package for the Social Sciences 22 (SPSS, Chicago, IL, USA) was used to analyse the data. For descriptive analysis, categorical variables were presented as frequencies and percentages, while continuous variables were described using mean and standard deviation. A paired t-test was used to compare the means of vital signs and lab tests before and after treatment. The Chi-square test was used to compare categorical variables (presence of fever and cough) before and after treatment. A \( P \)-value < .05 was considered to be statistically significant.

### 3 RESULTS

The study included 161 patients [52 (32.3%) women, 109 (67.7%) men] who were admitted with positive RT-PCR and clinical symptoms of COVID-19 (Table 2). The participants’ mean age was 44.3 (±17.0) years and average bodyweight was 81.3 (±9.6). The disease was prevalent amongst the middle age group (41-50 years). One-fifth of patients (19.3%) acquired the infection when they were visiting Iran. Approximately two-thirds (63.4%) of patients were infected by
contact with a family member, while 17 (10.6%) patients obtained COVID-19 from an unknown person. Some patients were healthcare providers/staff (6.8%) who were infected because of their work in hospitals. In terms of severity, 53 (32.9%) patients had mild condition, 47 (29.2%) had moderate condition, 35 (21.7%) had severe condition, and 26 (16.1%) had critical condition. Approximately, one-quarter (23.6%) of the patients were admitted to the respiratory care unit (RCU) (Table 2). All the 11 deceased patients were admitted in critical condition and had co-existing diseases.

The most common symptoms of COVID-19 patients at admission were cough (64.6%), headache (56.5%), shortness of breath (SOB) (47.2%), sore throat (41.0%), diarrhoea (36.6%), exertional dyspnea (32.9%), abdominal pain (31.1%), tiredness (31.1%), loss of appetite (29.8%), vomiting (23.6%), chest tightness (15.5%) (Table 3).

Most patients (84.5%) recovered and were discharged without symptoms after testing negative RT-PCR. However, 14 (8.7%) patients were discharged with mild symptoms (mild cough and/or exertional dyspnea). All recovered patients were required to be retested with RT-PCR 14 days after their hospital discharge.
Moreover, 11 (6.8%) patients died during the study period. Eight of them died before completing the five-day treatment course (six died within the first 24 hours and two died after 24 hours), while three died after one week of treatment in the intensive care unit (ICU) (Table 4). The deceased patients were admitted to the hospital in critical condition.

The average period of patient hospitalisation was 12.9 (±5.5) days. However, the duration of treatment was up to 14 days (for patients with pneumonia). The standard COVID-19 regimen which included hydroxychloroquine (HCQ) and azithromycin had a significant positive effect (P-value < .05) on patient body temperature, cough, SOB, respiratory rate (RR), pulse rate (PR), and fasting blood sugar (Table 5). In other words, those signs and symptoms of COVID-19 patients were reduced significantly after using a therapy regimen containing HCQ and azithromycin. However, there were non-significant effects of treatment (P-value ≥ .05) on systolic blood pressure (SBP), diastolic blood pressure (DBP), AST, ALT, ALP, total bilirubin, serum urea, and serum creatinine (Figures 1 and 2).

In terms of adverse drug reactions (ADRs), the most commonly reported ones were stomach pain/cramps, hypoglycemia, headaches, mood changes, dizziness, itching, diarrhea, muscle weakness, nausea, skin rash, vomiting, QT prolongation, arrhythmia, and conjunctivitis (Figure 3). Most ADRs were possible to be caused by HCQ and/or azithromycin. It means they also can be caused by the disease (COVID-19). Moreover, three ADRs including arrhythmia, QT prolongation and conjunctivitis were probably caused by the two medications (Table 6). In other words, they unlikely to be attributed to COVID-19 disease. The electrocardiograph (ECG) of six (3.7%) patients recorded QTc prolongation, but not more than 450ms. Additionally, arrhythmia was reported in three (1.9%) other patients (Table 6). The medical team stopped the HCQ and azithromycin treatment for three patients who experienced arrhythmia. Then electrolyte levels (calcium and potassium) were measured and corrected to treat the arrhythmia. However, this treatment stoppage occurred after completing the first five days of the therapy course.

### DISCUSSION

The pandemic of coronavirus disease 2019 (COVID-19) caused by the SARS-CoV-2 presents a challenge in terms of identifying effective drugs for prevention and treatment.\(^\text{14}\) HCQ has a long history as a safe and inexpensive drug for malaria and autoimmune diseases despite some eye and cardiac side effects.\(^\text{15}\)

During the study period (from March 1 to May 25, 2020) and before the exponential increase in COVID-19 cases in Iraq (>1000 cases/day) which started on June 5, 2020, admission to one of the MOH quarantine facilities was required by law for confirmed cases. Thus, all patients who tested positive were treated in government COVID-19 specialised facilities. The study centre was one of the 22 specialised COVID-19 centres across the country. The number of

| Arrhythmia                    | 3 (1.86%)  | probable      |

Note: Probable = Unlikely to be attributed to disease or other drugs. Possible = Could also be explained by disease or other drugs. Unlikely = Disease or other drugs provide plausible explanations.\(^\text{13}\)
participants in this study represents 3.5% of the total Iraqi COVID-19 cases during the study period. The therapy regimen was the same across all 22 specialised COVID-19 in Iraq as it was implemented by the MOH. According to the MOH therapy protocol, HCQ and azithromycin should be given for all COVID-19 cases and other anti-viral agents/antibiotics can be added for severe and critical cases. During the study period, the use of convalescent plasma to treat COVID-19 had not been started in the study setting.

In this study, the treatment regimen (containing both HCQ and azithromycin) appeared to help promote recovery in 150 COVID-19 patients (83.2%) in the study centre. Although 16% of patients were admitted in critical condition and 26% were admitted to the RCU, the mortality rate was only 6.8%. It is worth mentioning that most deceased patients were admitted in critical condition and died before receiving a full course of treatment. The same MOH therapy regimen facilitate recovery in 2,811 cases out of 4,632 COVID-19 patients in Iraq during the study period, and only 163 deaths (3.52%) were reported. This high recovery rate was probably because of the effectiveness of the treatment protocol and close disease monitoring by healthcare providers. They work hard despite several challenges facing the Iraqi healthcare system including a shortage in the number of quarantine facilities, a shortage in personal protective equipment (PPE) and limited RT-PCR testing.

The average hospitalisation period was 12.9 (±5.5 days) given there was a small number of admissions per day during the study period and no high demand for hospital beds. This duration may reflect the fact that about two-thirds of admitted patients developed pneumonia and needed time to recover. Moreover, all those who tested negative with RT-PCR on days 6 and 7 after admission were discharged on day 8. The results of our study were comparable to a French clinical trial to evaluate the role of HCQ and Azithromycin on respiratory viral loads in patients with confirmed COVID-19.

The study found a significant reduction of the viral carriage in the HCQ/azithromycin group compared with the control group at day 6 post-inclusion. The study reported 100% viral clearance in nasopharyngeal swabs with the combination of HCQ and azithromycin compared with 57.1% in HCQ alone group and 12.5% in patients who did not receive HCQ (P < .001). Chloroquine and HCQ appear to block viral entry into cells by inhibiting the glycosylation of host receptors, proteolytic processing, and endosomal acidification. These agents also have immunomodulatory effects through the attenuation of cytokine production and inhibition of autophagy and lysosomal activities in host cells. HCQ has in-vitro activity against SARS-CoV-2 with half-maximal effective concentration (EC50) of 6.14 μM which is lower than that of chloroquine (EC50 = 23.90 μM) after 24 hours of growth.

Moreover, some manageable side effects of HCQ were reported during the treatment period. These side effects may disappear during treatment as the body adjusts to the medicine. The reported side effects included stomach pain/cramps, hypoglycemia, headaches, mood changes, dizziness, itching, diarrhea, muscle weakness, nausea, skin rash, and vomiting. Those are common HCQ side effects and appear to be dose-dependent and most often occur with loading doses of 800 mg or higher. In this study, we used an HCQ maintenance dose of 400 mg daily for a short-term course which is relatively safe since the recommended daily dose was not exceeded. The most severe and life-threatening complications from the use of hydroxychloroquine include QT interval prolongation and the resultant risk of ventricular arrhythmias. In our study, the electrocardiogram (ECG) monitoring showed that six patients developed QT interval prolongation, but not more than 450ms which did not require medical intervention. In contrast, three patients developed arrhythmia and needed medical intervention which consisted of stopping the treatment and normalising the blood electrolytes (potassium and calcium). The incidence of QT interval prolongation with using chloroquine and hydroxychloroquine is highly dependent on baseline ECG findings, with risk exacerbated using concomitant QT-interval prolonging medications. The combination of azithromycin with HCQ frequently prolongs the QT interval in a clinically significant manner, increasing over time and requiring additional monitoring.

Chinese Centre for Disease Control and Prevention includes chloroquine in the treatment guideline for COVID-19 patients which gave a high recovery rate (94.5%). A recent study relying on a multinational registry analysis which was published on May 22, 2020, found no evidence of hydroxychloroquine effectiveness to treat COVID-19. However, this study was retracted after some expressed concerns about its findings. On March 28, 2020, the US FDA issued Emergency Use Authorisations (EUA) that allowed the use of hydroxychloroquine to treat COVID-19. On June 15, 2020, the FDA revoked this EUA because of the absence of scientific evidence. This controversy about using hydroxychloroquine to treat COVID-19 is because of the absence of findings based on well-designed randomised controlled trials (RCTs). Although there is a debate about the effectiveness and safety of using hydroxychloroquine, the new Iraqi guideline (on June 1, 2020) still includes HCQ to treat mild and moderate cases of COVID-19 since it has been showing promising results and because of the absence of superior alternatives, in addition to its affordability and availability.

This study had some limitations. It was conducted in a single-centre without a comparison group. Single-centre findings may not be generalisable. However, a universal therapy regimen has been implemented by the health top authority across all country healthcare settings. Lack of a comparison group can limit the determination of causality between the therapy and the cure or good prognosis. Additionally, some disease-induced symptoms overlap with ADRs during treatment period.

5 | CONCLUSIONS

This natural trial showed that the COVID-19 regimen containing both HCQ and azithromycin is helpful in treating the majority of patients and reduced their signs and symptoms significantly. It also causes some manageable side effects mostly those related to heart rhythm. In the absence of FDA-approved medications to treat COVID-19, the repurposing of HCQ and azithromycin to control the disease signs...
and symptoms is potentially useful. The study showed that using this therapy combination (HCQ and azithromycin) is promising and can fill the gap until more effective treatments are found. Future randomised controlled trial can give more definite answers about the effectiveness and safety of such therapy protocol.

ACKNOWLEDGEMENTS
The authors would like to thank Dr Jawad Rasheed, Dr Ali AL-Garrawy and all the physicians and healthcare provider in Al-Shi’afaa Centre for Corona pandemic at Medical City, Baghdad who helped the research team conduct the study. If they had not bravely risked their lives to treat the COVID-19 cases, there would not be such a high recovery rate amongst patients.

CONFLICT OF INTEREST
No conflict of interest to declare and the study received no fund.
